described above. Parasagittal images (figs 2, 3) demonstrated a sizeable blood clot in the posterior extradural space. This clot extended upwards from the injection site to the T11–12 intervertebral space and down one interspace to the L2–3 level. The clot was largest at the levels of the intervertebral discs, where the sagittal diameter of the spinal canal is greatest (figs 2, 3). The clot caused considerable mass effect, compressing the thecal sac and displacing the conus medullaris and the upper cauda equina anteriorly and to the right (fig. 4). Axial images at T11–12, T12–L1 and L1–L2 (fig. 5) also demonstrated clot extending out through the lateral recess into the neural exit foramina on the right side, with anterior displacement of the exiting nerve roots.

In addition to the focal clot at the injection site, a thin irregular layer of more mature clot was present, extending down the posterior aspect of the thecal sac into the upper part of the sacral recess (fig. 3) and anteriorly into the anterior extradural space.

There was considerable change in the intensity of the CSF within the subarachnoid space after the blood patch. CSF normally appears black on T1 weighted images (fig. 1); however, after blood

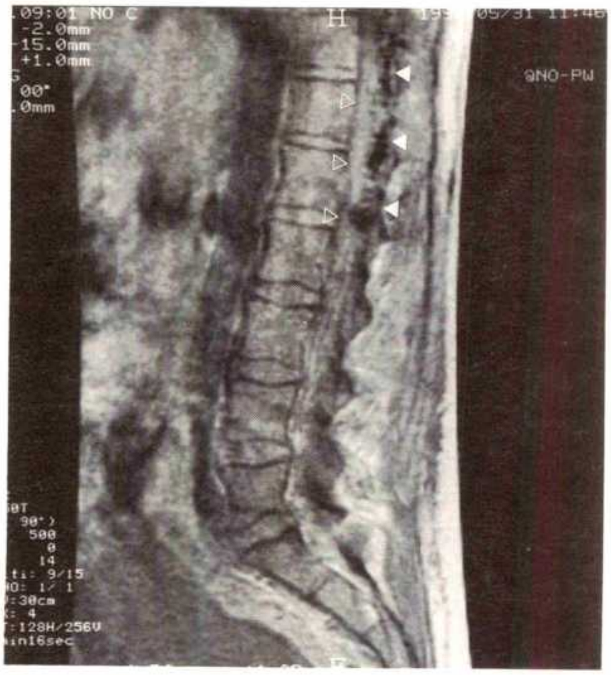

FIG. 2. Midline sagittal section (GE 500/14/90) after blood patch showing extensive blood clot (arrow heads) displacing the conus medullaris and cauda equina (open arrow heads) anteriorly.

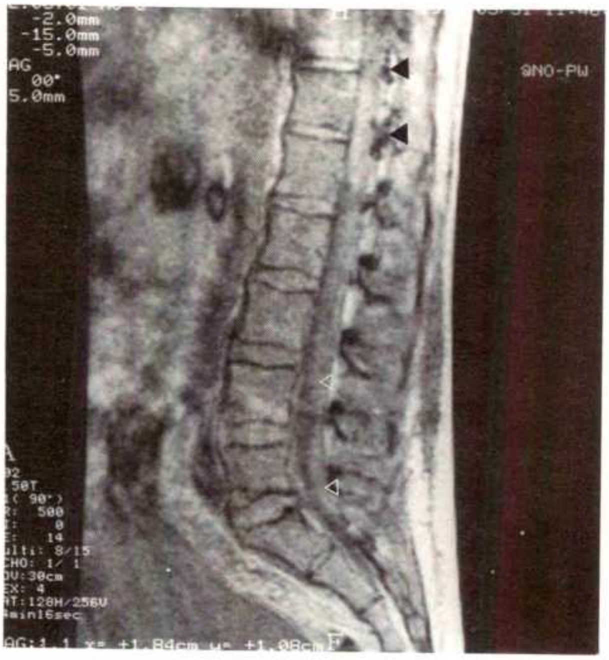

FIG. 3. Parasagittal section showing the distribution of developing clot (black areas) at the levels of the intervertebral discs (black arrowheads). Caudal spread of more mature haematoma (grey areas) is also demonstrated (open arrowheads).

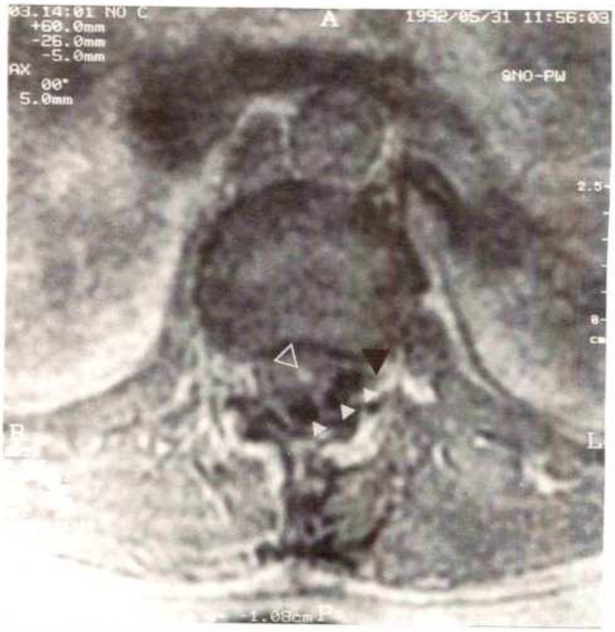

FIG. 4. Axial image at the level of the T12–L1 intervertebral disc showing clot (small arrowheads) displacing the thecal sac, conus medullaris (open arrowhead) and left D12 nerve root (black arrowhead) within the exit foramen.

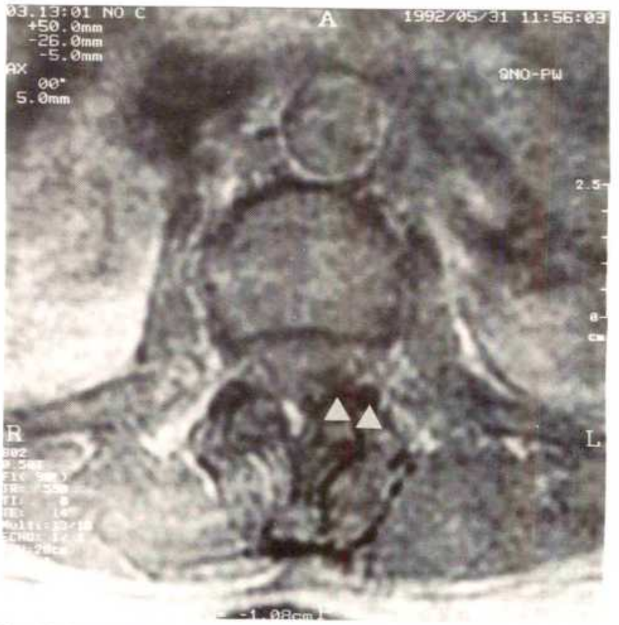

FIG. 5. Axial image at the level of the L1–2 disc showing high signal from CSF, indicating subarachnoid spread of blood and extension of clot (arrowheads) through the intervertebral foramen.

described above. Parasagittal images (figs 2, 3) demonstrated a sizeable blood clot in the posterior extradural space. This clot extended upwards from the injection site to the T11–12 intervertebral space and down one interspace to the L2–3 level. The clot was largest at the levels of the intervertebral discs, where the sagittal diameter of the spinal canal is greatest (figs 2, 3). MUSCULAR PARALYSIS AND VENTILATORY FAILURE CAUSED BY HYPERKALAEMIA

S. J. FREEMAN AND A. D. FALE

SUMMARY

We report the history of a diabetic man presenting with hyperkalaemia and rapidly progressing muscular paralysis with severe respiratory embarrassment. His symptoms resolved rapidly with reduction of the serum potassium concentration. Similar cases have been reported previously but this is a problem that few will have encountered and is a diagnosis which should not be overlooked before artificial ventilation is commenced. (Br. J. Anaesth. 1993; **70**: 226–227)

KEY WORDS

Complications: hyperkalaemia. Complications: paralysis. Ventilation: failure.

CASE REPORT

A 75-yr-old man was admitted with a short history of progressive ascending muscular weakness. He had a history of maturity onset diabetes mellitus, severe peripheral vascular disease with a right femoro–popliteal bypass and benign prostatic hypertrophy for which he had undergone TURP 2 months before admission, when his serum creatinine concentration was normal (98 μmol litre^{-1}).

His usual drug treatment was glibenclamide 5 mg twice daily and metformin 1 g twice daily. One week before admission, he was prescribed amiloride–hydrochlorothiazide (Moduretic) tablets one daily for peripheral oedema.

Thirty hours before admission he had noticed difficulty getting up from a chair, which had progressed rapidly to global muscle weakness. He had not noticed any sensory symptoms or sphincter disturbance and his history gave no suggestion of a recent viral illness.

On examination, he had profound muscle weakness of arms and legs (proximal muscles MRC grade 1/5; distal muscles MRC grade 0/5), together with difficulty talking and breathing. His peak ventilatory flow rate was 70 litre min^{-1}. There was marked muscular fasciculation in the arms and legs, reflexes were depressed and plantar responses absent. He had a "stocking" loss of sensation to below the knee, mild background diabetic retinopathy, but no cranial nerve abnormalities.

A presumptive diagnosis of acute postinfective polyneuritis was made and he was transferred to the ICU for tracheal intubation and mechanical ventilation of the lungs.

Investigations

ECG showed broad QRS complexes with peaked T waves, biochemistry showed serum concentrations of sodium 127 mmol litre^{-1}, potassium 10.2 mmol litre^{-1}, chloride 101 mmol litre^{-1}, bicarbonate 17 mmol litre^{-1}, urea 18.6 mmol litre^{-1}, creatinine 207 μmol litre^{-1}, glucose 22.0 mmol litre^{-1}. Arterial blood-gas analysis revealed pH 7.29, $P\text{CO}_2$ 4.4 kPa, $P\text{O}_2$ 13.6 kPa, base excess −9 mmol litre^{-1}. CSF pressure was 15 cm H_2O, protein 166 mg litre^{-1} (ref. 155–450), glucose 8.6 mmol litre^{-1}, WBC $< 1 \times 10^9$ litre^{-1}.

Treatment and progress

There was a dramatic response to treatment with i.v. calcium gluconate, an insulin and glucose infusion and i.v. sodium bicarbonate. Within 20 min he was able to lift both hands above his head and his peak ventilatory flow rate had increased to 350 litre min^{-1}. Treatment was continued with an insulin–glucose infusion, oral calcium resonium and fludrocortisone which was withdrawn after 12 days. His serum potassium concentration fluctuated over the next 36 h mirroring changes in his peak expiratory flow rate, but then settled within the normal range. He was discharged and, at follow up 10 days later, was well, with normal serum electrolyte and creatinine concentrations. Ultrasound showed normal kidneys with no evidence of obstruction. He had normal liver function tests and serum calcium concentration and a normal response to a short synacthen test.

DISCUSSION

Both hypo- and hyperkalaemia can produce a clinical picture of flaccid muscular paralysis very similar to that of acute postinfective polyneuropathy (Guillain–Barré syndrome) and the importance of measuring the serum potassium concentration and recording an ECG early in the investigation of suspected acute postinfective polyneuropathy has been emphasized [1, 2]. In our patient, rapid recovery of muscle power after emergency treatment of

the hyperkalaemia, combined with normal CSF confirmed that hyperkalaemia was the cause of his paralysis.

Although cardiac arrhythmias are the usual cause of death in severe hyperkalaemia, muscular weakness may be the predominant manifestation, with ventilatory failure a potentially lethal complication, as in our patient, and occasionally artificial ventilation may be needed [3]. The use of suxamethonium as a rapidly acting neuromuscular blocker is associated with an increase in serum potassium concentration [4]; this increase may precipitate arrhythmias.

The dangers of using potassium-sparing diuretics in elderly patients, who may have some degree of renal impairment despite normal serum creatinine concentrations, are well known. Hyperkalaemia after treatment with amiloride–hydrochlorothiazide combinations has been reported previously [5]. In our patient, the period of hyperkalaemia correlated well with the duration of action of amiloride, started 1 week before presentation, and emphasizes the importance of early biochemical monitoring after starting treatment with a potassium-sparing diuretic in the elderly.

HISTORY

JOHN HENRY HILL LEWELLIN: THE FIRST ETHERIST IN GLASGOW

A. G. MACDONALD

SUMMARY

John Henry Hill Lewellin, a surgeon–dentist, was the first to administer ether in Glasgow, on January 4, 1847. He was born in Calcutta, trained at St Bartholomew's Hospital, qualified M.R.C.S. in London in 1842, and studied in Paris and Heidelberg, before moving to Glasgow in December 1845. He remained there for about 18 months, advertising his dental practice in a high profile manner and, when the time came, he publicized his experience with ether in the local press in an exemplary way. He disappeared from Glasgow in June 1847, and reappeared in Australia 5 years later, practising as a dentist initially, and later as a general medical practitioner in Melbourne until his retirement in 1883. He died in 1886. (Br. J. Anaesth. 1993; **70**: 228–234)

KEY WORDS
History: diethyl ether.

William Morton's historic administration of ether to Gilbert Abbot on October 16, 1846 in the Ether Dome of the Massachussett's General Hospital in Boston preceded the first administration in Britain by 9 weeks. The manner by which the news travelled from Boston to London, and independently from Boston to Dumfries, is well documented [1, 2]. James Robinson and Francis Boott administered ether to Miss Lonsdale for the removal of a firmly fixed molar tooth on Saturday, December 19, 1846 in Boott's house at 42 Gower Street, London and on the same day, in the Dumfries and Galloway Royal Infirmary, Dr William Scott operated on a patient who was under the effect of ether, having learned of the discovery from Dr Fraser, the ship's doctor on the "Acadia". There are few details about the Dumfries case, as the relevant hospital records are missing and, indeed, there almost seems to have been a cover-up over the episode, making one wonder if the administration of ether in that case went badly.

From London to Scotland

During the subsequent 2 weeks, the news of the discovery of ether also reached Scotland by private correspondence and by the daily newspapers. Robert Liston, the Scottish surgeon who had performed the first surgical procedure under ether in England at the University College Hospital, London, on Monday December 21, had corresponded with James Millar, Professor of Surgery in Edinburgh, and this resulted in the first use of ether in Edinburgh taking place in the Royal Infirmary on Saturday January 9, 1847 [3], when Dr James Duncan performed a thigh amputation on a young man who had been involved in a railway accident [4].

First use of ether in Glasgow Royal Infirmary

The first use of ether in Glasgow was thought to have taken place at The Royal Infirmary towards the end of January 1847, when Professor James Lawrie was reported to have performed several operations on patients who were under ether, although no exact dates or details are given [5]. It is probable that this initial use of ether in Glasgow took place on January 27, and was witnessed by Benjamin Ward Richardson, who was a medical student at the time, having begun his studies at Anderson's College in 1845. In his memoirs, published many years later [6], he describes the occasion vividly. He records that a Dr Fleming gave the ether vapour "from a sponge surrounded by a towel", and that Professor Andrew Buchanan did the operation, in the presence of Professor James Lawrie and Professor Moses Buchanan, Professor of Anatomy. This trial of ether was entirely successful, and ether administration soon became accepted in Glasgow. Unfortunately, no dates are recorded in these memoirs. Four further operations were performed under ether on Wednesday February 10, and were described in detail in the local press [7].

The discovery of Lewellin

All the newspaper articles relating to the introduction of ether at Glasgow Royal Infirmary had appeared in the *Glasgow Herald*. There were, however, seven daily newspapers in Glasgow in 1847, although only the *Herald* has survived. They were mostly four-page broadsheets, published twice or three times weekly. Articles printed in one newspaper often appeared in the others a few days later. This also applied to articles from the national newspapers, which were occasionally reprinted in full. For some strange reason, the *Herald* failed to

ALAN G. MACDONALD, M.B., CH.B., F.R.C.ANAES., M.R.C.P.GLASG., Department of Anaesthesia, Victoria Infirmary, Glasgow G42 9TY. Accepted for Publication: August 5, 1992.

copy the reports which had appeared in the *Glasgow Courier* and the *Glasgow Argus*, announcing the earlier use of ether in Glasgow.

The first that Glasgow readers knew of the discovery of ether was the report of the *Glasgow Courier* of January 1, 1847 [8], which contained the entire reprint of the famous article from the *Medical Times*, headed "Surgical Operations without Pain", which began: "We have been informed that two operations were performed by Mr Liston at University College Hospital on Saturday last...".

On January 5 [9], the *Courier* published an extract of Dr Bigelow's publication in the *Boston Medical and Surgical Journal*, which had appeared in the *Morning Chronicle* a few days before, describing in detail his experiences with 10 patients given ether. This long article provides enough information to enable anyone to go away and administer ether himself, and yet it was several weeks before Dr Lawrie used it in the Glasgow Royal Infirmary.

The *Glasgow Argus* of January 11 [10], under the heading "New Discovery in Surgery", printed an article from *Punch*, in which the writer caricatures the new miracle: "a man may have his legs cut from under him without his knowing it,...while the drawing of teeth becomes an agreeable excitement, which is so delightful that a boy having been mulcted of a molar clamoured loudly to have another extracted". This article, too, might have stimulated Glasgow surgeons to try ether, but it was another 2 weeks before they did so.

The *Herald* of January 15 [11] described Dr Duncan's first use of ether in Edinburgh—another prompt, which again had no immediate effect.

The *Courier* of Saturday January 16 [12] produced an unexpected discovery. Under the heading "Dental Surgery", an article described the use of ether by a Mr Lewellin, a Glasgow dentist, on a 23-yr-old man for the extraction of an upper molar. It is an impressive description of the procedure, revealing a scientific approach to the administration of this new agent. It describes how the inhalation continued for 2 min, being complicated slightly by the patient swallowing at one stage instead of inhaling, how the heart rate increased from 64 to 80 beat min^{-1}, and how the face became slightly flushed. It also comments that "not the least attempt at coughing as observed in the American experiment" took place. Presumably Mr Lewellin had read Bigelow's article. He also says how the tooth, of a particularly bad shape and in a difficult locality, was removed without pain. He finished by inviting anyone to come to witness the new technique.

Twelve days later, on January 28 [13], again in the *Courier*, another communication from Lewellin appeared, written two days earlier. This was a letter to the Editor, under the heading "Use of Ether in Dental Operations". It referred to a notice in the *Courier* of January 26, which apparently had stated that ether had first been used in Scotland on January 5. Lewellin made it quite clear that he had used ether one day earlier, on January 4. He added that the equipment used was similar in principle to that used in London (so he must have had knowledge of Squires' inhaler), and that the administration was witnessed "by several gentlemen, medical and scientific, as well as friends of the patient, and it was at their instigation that the case was brought before the public".

Lewellin demonstrated in this article an impressive awareness of many of the finer points of administering ether. He urged caution in not using the agent in all cases, he warned about the dangers of leaving it exposed to air and light, and he described how its toxic metabolites might injure the texture of the lungs.

He finished "I merely state these facts knowing that ether will and must become general in dental surgery for which it is peculiarly applicable, and as the greater number of dentists are not properly qualified medical practitioners, and consequently ignorant of the circumstances. With many apologies for having trespassed so far on your space, I am sir, Your obedient Servant, J. W. H. Lewellin, MRCSS, 86 West Regent Street, 26th January 1847".

This was a confidently written letter, composed in an educated and authoritative style. No doubt, his inference that most of his colleagues were less well qualified than he was would not have endeared him to many.

The M.R.C.S.S. did not appear in the lists of recognized qualifications, but was almost certainly a Membership of a Royal College (see later).

Buchanan's unsuccessful claim

The *Courier* of January 26 [14], which Lewellin had referred to, revealed an obscure paragraph, easily missed, and under a misleading heading. This stated that Mr Buchanan, another Glasgow dentist, "has introduced the vapour of ether in his practice", and that he was "the first to employ this powerful new agent in Scotland, having used it on the 5th inst". It also mentions that the apparatus used on this occasion was a bent glass tube. This piece of equipment was almost certainly the apparatus devised in December 1846 by George Buchanan of Glasgow, a cousin of this dentist, who later became Professor of Clinical Surgery in Glasgow. It is slightly confusing that both cousins had the same name, but, in his article published 51 years later [15], George Buchanan recounts how his dentist cousin had received a letter on December 22 1846 from a friend in London who had witnessed Liston's first operation under ether the day before. That same evening, he and his cousin, in the presence of his father, had experimented with ether at their home, using the bent glass tube with a bulb in the middle. There can be little doubt that this experiment must have been the first self-administration of ether in Scotland. It is remarkable also to think that, in those days, a letter posted in London on December 21 could have reached Glasgow the following day.

There is no further correspondence after Lewellin's second letter, so Buchanan must have conceded victory to Lewellin. One cannot help feeling sympathy for Buchanan, as the *Argus* of January 21 [16]—7 days before Lewellin's first announcement in the *Courier*—revealed that Buchanan actually advertised his "ETHER INHALER, similar to what has been recently used in London by

Robert Liston, Esq. and others with such eminent success. By this process the most painful operations may be performed without inconvenience to the Patient". This was therefore in print 5 days before his claim to be the first etherist in Scotland. Buchanan does not state in his advertisement that he had *actually* used the inhaler himself, although he clearly *had* done so on January 5. Nevertheless, he gets the credit of being the first to advertise the use of ether in Glasgow.

How did Lewellin hear of the discovery of ether?

The detailed account of Bigelow's experiences of ether appeared in the *Courier* on January 5, the day after Lewellin's first administration. So he must have heard about ether from another source, perhaps directly from Buchanan, or from someone in Edinburgh who knew of Liston's letter to Millar. He may even have received a personal letter from one of his London colleagues who knew of the discovery.

Another source of information was the medical journals. The first issue of the *Lancet* of 1847 was published on Friday January 1, and would have been despatched a day or two earlier. That issue contained three letters from Dr Boott to the Editor [17]. The first was a covering letter with a copy of Bigelow's personal communication to him, relating in detail his experiences with ether. The second described Robinson's extraction of Miss Lonsdale's tooth in his presence, and the third was another covering letter enclosing a letter from Liston, recounting his first two successful administrations of ether, and thanking Boott for having given him such early information of the discovery. These articles provide full details of the apparatus used and the technique of administration of ether. If Lewellin was a subscriber to the *Lancet*, he might have received this issue on or before Saturday 2, in time to study it, and to prepare for his first use of ether on Monday 4.

Lewellin advertises his use of ether

The *Glasgow Argus* of February 1, 1847 [18], only three days after Lewellin's letter claiming to be the first etherist in Scotland, contained an advertisement headed "Mr LEWELLIN, Member of the Royal College of Surgeons, London, Member of the Royal Parisian Medical Society, Surgeon Dentist". This was a more substantial announcement than Buchanan's, and informed the reader that he had devised a new and better apparatus for the administration of ether, and that he was able to regulate the dose to suit each individual. It concluded "Advice *Gratis to the Poor* from 9 to 10 every Morning except Sunday". This advertisement appeared in the *Argus* every Monday for 6 weeks, and was then replaced on April 11 [19] by an even larger one, which appeared every 2 weeks until June 21 [20]. After this date, no further evidence of Lewellin's existence in Glasgow has been found. His Membership of the Royal Parisian Medical Society is discussed later.

Lewellin's ostentatious advertising stimulated some of his dental colleagues to do likewise. One sounded reluctant at being pressurized into this: "Mr Greig... has been advised to take this mode of acquainting his Friends, that he, among others, has in several cases successfully employed the ETHER INHALER under operations" [21]. One can imagine how Lewellin's style of practice may not have pleased his rivals.

Lewellin's earlier advertising

A further search of the Glasgow newspapers of 1845 and 1846 revealed that Lewellin had begun advertising his dental practice long before ether came on the scene. His first advertisement appeared in the *Herald* on December 15 1845 [22]. It indicated that he had "lately arrived from Paris", having studied there, in some principal German Universities, and in London.

In another column of the same page of that issue of the *Herald*, there was another advertisement, headed "Avis aux Etrangers", which, in immaculate French, advised its readers that Mr Lewellin had recently arrived from Paris, where he had, for a long time, been attending courses run by its most distinguished Professors.

There was still more to come. In a third column of the same page of that now historic issue of the *Herald*, there appeared yet another advertisement, which began, "Herr Lewellin, MRCSL, Zahnarzt...", and, in very accomplished but formal German, drew attention to his years of studies in Germany and France, and to his familiarity with foreign and English methods of treatment, and declared his confidence "that he will be able to serve a most distinguished clientele always to their utmost satisfaction".

This behaviour of Lewellin was quite extraordinary, not only because of the multi-linguistic advertising used, which was surprising enough, but also in the conspicuous and high profile manner in which it was presented. Lewellin seemed intent on attracting an up-market clientele to his new practice. He may have expected there to be a growing French and German speaking population in the business and professional community of Glasgow at the time, as trading links with the mainland of Europe and the Baltic were developing fast. Glasgow was, after all, the "Second City of the Empire". However, it was unusual for dentists in Glasgow to indulge in advertising, and it is apposite to note that Lewellin's advertisements appear amongst those for Furniture Sales, Winter Hosiery, Railway Notices, Pig Iron Sales and School Holiday Dates. His advertisements continued to appear regularly throughout the next year, up to the time that he used ether.

The Royal Parisian Medical Society

The Parisian Medical Society was founded in November 1837, mainly for the benefit of British and American doctors who had come to Paris to complete their medical training. The 18 founder members were almost all members of the Royal Medical Society of Edinburgh.

An address, delivered by the Vice-President of the Society in April 1841, summarized its history, and re-affirmed its aims [23]. It stated "A visit to the Parisian University is now considered the necessary completion of a sound professional education". It is clear that one of the Society's aims was to co-ordinate the training of doctors from overseas. The membership in 1841 is recorded as being nearly 300—clearly a flourishing concern—and it was into this Society that Lewellin was presumably accepted a few years later. By that time it had become the Royal Parisian Medical Society. No records of its Proceedings have been traced, and it is likely that it was incorporated into another larger Association. It is not known therefore what part, if any, Lewellin played in its affairs, but he clearly thought it a prestigious enough Society to declare his membership of it when he began advertising his services in Glasgow a few years later.

Lewellin in Glasgow

The *Glasgow Postal Directories* of 1846 and 1847 listed Lewellin as Surgeon Dentist, 86 West Regent Street, and in 1847 his name was included in the list of 13 Dentists, all of whom resided within a few blocks of each other. Lewellin did not appear in earlier or later Directories, so it seems that he was based in Glasgow for only 2 years. The *Annual Census* lists of 1841 and 1851 for both Glasgow and London did not include Lewellin.

It seemed likely that Lewellin would have involved himself in the local dental and medical circles of the time. However, there was no Glasgow Dental Society in 1847, and the Glasgow Dental Hospital was not opened until 1879. His name did not appear in the Minutes of any of the Medical Societies of the time, the Royal Medico-Chirurgical Society of Glasgow, founded in 1814, or the Glasgow Southern Medical Society, founded in 1844. The records of the Glasgow Trades House, to which Barbers and Surgeons were affiliated, made no mention of Lewellin.

Lewellin's residence in Glasgow

Lewellin was showing considerable drive and determination in his quest to build up his dental practice in Glasgow. His residence in Glasgow was in the "New Town", that part of the city extending up Blythswood Hill from Buchanan Street, a prosperous and vibrant community, "on a very splendid scale, bearing comparison with those of any city in the Empire" [24]. West Regent Street was a new terrace of houses built in the 1830s, and No. 86 was a three-storey house on the corner of Hope Street. The houses were renumbered in 1920, but there is no doubt that Lewellin lived and practised in the building now occupied by the Yorkshire Building Society.

The search for Lewellin's origins

The very first *Medical Directory*, published in 1845, reveals "Lewellin, John Henry Hill, S1842, East Indies". The initials do not correspond with those in the *Courier*, which were incorrect. The possibility of Lewellin being related in some way to Henry Hill Hickman, is an enthralling thought, but as Hickman died in 1830, and as Lewellin's age was not yet known, it is pure speculation to imagine that they might be cousins. "S 1842" signified Membership of the Royal College of Surgeons of London, 1842. "MRCSS" in the *Courier* should have read "MRCSL": Lewellin's handwriting had been misread.

The *List of Fellows and Members of the Royal College of Surgeons in London* of 1848 records Lewellin as having passed his examination on April 8, 1842, and in the Examinations Register for that day, his name appears, showing his origin as East Indies, and his exam fee of £21 which, in the currency of the day, was 20 guineas.

An obscure section in the *Medical Directory* of 1872, under "Practitioners Resident Abroad with British Qualifications", listed "Lewellin, John Henry Hill, Prahran, Victoria, Australia, MRCS, England, 1842".

In 1874, his listing included the information that he had trained in St Bartholomew's Hospital, London, and also Paris and Heidelberg. It also recorded that he was a Justice of the Peace, and Vaccination Officer of Gardiner and Caulfield, which were Districts of Melbourne. He was appointed magistrate for the Colony of Victoria in 1868 [25]. He must have been resident for some years and have been held in high esteem to have gained these appointments.

In 1878, the Directory added "South. Rifles". Lewellin was appointed Assistant-Surgeon to the Southern Rifles with the relative rank of Lieutenant in January 1864, and was posted to the Prahran and South Yarra Corps [26]. He was promoted Captain in 1867 [27], and by 1878 he had gained the rank of Major [28].

In 1882, another Lewellin was listed: Augustus John Richard Lewellin, Prahran, Victoria, MB 1873, LKQCP, Ireland. This was Lewellin's son, who had almost certainly joined the family practice.

In 1883, the father's name disappeared, but the son's continued. No Obituary appeared in the Lists of Deaths which were, until 1914, included in these *Medical Directories*.

St Bartholomew's

The Students' Register for those studying at St Bartholomew's Hospital in the academic year 1842–43 shows Lewellin's signature, denoting his acceptance of the terms, conditions and rules of the Medical School. It did not record how long he attended, but it did provide two addresses, 40 Gibson Street, Islington, and Fort William, Calcutta. The former was almost certainly his lodgings during his time at St Bartholomew's, and the latter his home origins in the East Indies.

Fort William was the name given to the Army garrison on the banks of the River Hooghli (sometimes now spelt Hugli) in Calcutta. The Old Fort was built in the late 17th Century to protect the English traders from attack from the Nawab of Bengal [29]. The Fort was rebuilt in 1781, and became a training ground for British troops. It was likely that Lewellin's family was based in this garrison.

Lewellin's family

The *Ecclesiastical Returns of the Fort William Garrison*, of 1819, recorded the birth of John Henry

Hill Lewellin on September 18, 1818, and his baptism on May 24 1819 by John Young, garrison Chaplain. Lewellin's father was recorded as Lieutenant Henry Lewellin, of His Majesty's 24th Light Dragoons, and his mother as Anne Eliza.

There is a mystery concerning Anne Eliza. In the Schedule recording John Henry Hill's death [30], his mother was named as "Eliza Anne Lewellin, m.n. (maiden name) Farquhar or Farquharson". This conflicts with the records of her first marriage at Cawnpore, to William Lambert, in which she was named as Anne Eliza Smith, Spinster [31]. No information has yet emerged to resolve this discrepancy, but if her maiden name really was Farquhar or Farquharson, both Scottish names, this might provide a family reason for Lewellin coming to Scotland in 1845. Perhaps she gave an assumed name "Smith" to the Registrar in Cawnpore.

Lewellin in Australia

Lewellin arrived at Port Phillip, Australia on the 500-ton teak-built ship "Bengal Merchant" on September 2, 1852, 5 years after the last reference to him in the Glasgow newspapers in June 1847. The ship left London on April 1, and called in at Port Elizabeth, South Africa, on July 26 [32]. The "Bengal Merchant" appeared in an advertising poster of 1839, intimating its imminent departure from the Broomielaw Pier, Glasgow, taking passengers and cargo to New Zealand and The Colonies.

Lewellin's name appeared in the *Medical Register for the Colony of Victoria* from 1854 until 1886, and he was listed in a Melbourne *Directory* for 1858, as a dentist practising at 94 Collins Street, Melbourne [33]. A casual comment in one of his publications, in 1856 [34], stated ".. as I have now given up general practice and confine myself to Dentistry". It is not known if he was in general practice when he first arrived in Australia, or before he emigrated.

In 1861, he was listed as a surgeon, practising at 116 Chapel Street, Prahran [35]. Lewellin may by this time have been a general practitioner, perhaps conducting a mixed practice, including dentistry.

Lewellin's publications in Australia

Although Lewellin's name appeared only sporadically in the Australasian medical journals from 1856 onwards, the following three articles are of interest:

In 1856, Lewellin's address to the Medical Society of Victoria on "Acute Dysentery" was published in full [34].

In 1860, Lewellin presented a long and complex Case Report of "Pneumo-Hydro-Thorax" to the same Medical Society [36].

In 1863, Lewellin published a remarkable Case Report of a 12-year-old boy with tetanus [37], a condition for which the outlook in those days was hopeless. The boy developed hourly paroxysms of his back muscles, and Lewellin considered it advisable to remove a decayed tooth, which was acting as a source of irritation. He administered chloroform, and when the boy "was thoroughly under its influence, the rigidity abated sufficiently to allow me to get his mouth wedged open with a piece of soft wood, so that I extracted the first upper permanent molar of the left side, which was very much decayed. The second temporary molar of the lower jaw being also decayed, I removed that". The boy was so much improved as a result of the chloroform administration, that it was repeated at regular intervals every day for the next 12 days. During one of these administrations, Lewellin removed another decayed tooth. Chloroform undoubtedly resolved the spasms and delayed the onset of further spasms. On the 13th day, Lewellin recorded that paroxysms were becoming less frequent, although "he cannot do without chloroform". Ten days later, the boy "has become so fond of it that he flew into a passion when it was refused him". The boy appears to have recovered completely (no mention of hepatic necrosis!). This Case Report is notable for the diligent manner in which Lewellin attended his patient, and the determination with which he persisted with his treatment. This unique use of chloroform in the treatment of tetanus would only have been used by someone well versed in the problems of anaesthesia. There is no evidence that Lewellin had maintained his anaesthetic skills; indeed, the article gives the impression that he was now a General Practitioner.

Lewellin's friendship with Ferdinand von Mueller

Lewellin and his family became personal friends of the distinguished Botanist, Ferdinand von Mueller, who was born in Rostock, Germany and had, like Lewellin, emigrated to Australia. Mueller dedicated Volume 8 of his best known work, *Fragmenta Phytographiae Australiae* [38], to Lewellin, with a Latin inscription, which, translated, means "To my friend Henry Lewellin, a most skilful Physician".

Mueller named two plants after Lewellin: a shrub, named *Dicrastylis Lewellinii* [39], also called Purple Sand Sage [40], and a fungus, *Hygrophorus Lewellinae* [41]. In Volume 11 of *Fragmenta*, there is another reference to Lewellin [42], again in Latin, which translates ".. dedicated in gratitude to the distinguished Dr Henry Lewellin, the most generous promoter of my investigations"; Lewellin must have been sponsoring his friend's botanical studies.

Lewellin's death

Lewellin died on October 12, 1886, at his residence, Linton, Westbury Street, East St Kilda, Melbourne, in his 69th year [43, 44]. The Death Certificate, which recorded him as "Surgeon", indicates that he died three days after a hemiplegia, complicated by epileptic convulsions. It records his marriage in London, aged 26 years, to Grace Elizabeth Donnelly. She died in St Kilda, on August 7, 1888, aged 63 years [45]. She would have been 19 when she married Lewellin in 1844. It establishes that Lewellin was already married when he came to Glasgow in 1845. They had seven children.

Why did Lewellin move from Paris to Glasgow?

If Lewellin came directly from Paris to Glasgow in December 1845, he was leaving a city which was experiencing widespread social unrest. The working classes were being driven to the utmost limits of their resources. Lewellin may have sensed that civil war was imminent. Glasgow in 1845 would have provided a stimulating environment for any professional young man.

Why did he leave Glasgow in July 1847?

One can imagine many reasons why Lewellin left Glasgow. Perhaps his practice had not flourished. Perhaps he had upset his dental colleagues. Perhaps he was suffering once again from the wanderlust which seems to have been his hallmark during these early years. Perhaps it was the smoke and the climate that chased him away. Glasgow in 1847 was experiencing severe civil discontent, precipitated by deteriorating living conditions in many parts of the city, made worse by the large influx of Irish immigrants, after the potato famine of 1845. The poor were starving. There was no social support. Law and Order was beginning to break down, and the Bread Riots brought serious disruption to the city.

It is not yet known where he and his wife went for the next 5 years, but, with his entrepreneurial personality, it would almost certainly have been somewhere professionally stimulating. Australia and Melbourne would have fitted that category very well, but it was to be a further 5 years before he and his family landed at Port Phillip Bay.

Epilogue

The story of John Lewellin's life and career is incomplete. It is not known when he left Calcutta with his mother and brother, or where he lived until 1842, when he studied at St Bartholomew's. It is also not known when or for how long he was in Paris, Heidelberg, or the other European centres at which he studied. The most disappointing and frustrating gap is the 5-year period from June 1847 when he left Glasgow until September 1852 when he arrived in Australia.

The life of Lewellin provides an interesting, and at times exciting, tale of an enterprising pioneer. He showed initiative, by travelling around Europe to gain the widest experience by training in the most advanced centres. He showed charisma, by his conspicuous and flamboyant advertising of his dental skills during his time in Glasgow. He demonstrated courage, by being the first in Glasgow to administer ether in dental practice, integrity, by bringing his own experiences so promptly to the notice of the public, and remarkable clinical insight, by the perceptive observations which he recorded in such detail. He continued to display this dedicated approach to his work as a general practitioner in Australia, where he maintained his active role in medical affairs.

John Henry Hill Lewellin deserves credit and commendation for all these attributes. He has the distinction of being the first to have administered ether to a patient in Glasgow. If William Scott's anaesthetic to his patient in the Dumfries and Galloway Royal Infirmary on Saturday December 19, 1846 did indeed go badly wrong, then perhaps John Lewellin administered the first successful anaesthetic in Scotland on Monday January 4, 1847.

ACKNOWLEDGEMENTS

I have great pleasure acknowledging the help I received from three Australian colleagues: Professor John Pearn, University of Brisbane, Dr Gwen Wilson, Royal Australasian College of Surgeons, and Dr Richard Gillespie, University of Melbourne. I am most indebted to them for their interest and encouragement.

I am also grateful to Dr Derek Dow, Archivist to the Greater Glasgow Health Board; Dr Richard Ellis, St Batholomew's Hospital; Miss Elspeth King, Deputy Keeper of Local History, Glasgow Museums and Art Galleries; Mr Ian Lyle, Librarian at The Royal College of Surgeons of England; Dr Henry Noble, Glasgow Dental Hospital and School; Miss Judy Macdonald, State Library of Victoria, Australia: Dr Tom Boulton, Honorary Archivist to the Association of Anaesthetists of Great Britain and Ireland; and Dr Anima Banerjee, Calcutta, for providing the booklet, *The Fort*.

I wish to thank sincerely my colleagues in the Victoria Infirmary who assisted in the secretarial, research and photographic needs of this paper: Mrs Sheila Grant, Anaesthetic Department Secretary; Miss Sheila Murdoch, previously Librarian; and Mr Ian Taylor and his colleagues in the Medical Illustration Department. I am grateful also to Mrs Clare McMillan, Dorking, and Mrs Betty Thomson, Richmond, for research assistance; to Miss Anne Welsh and Mr Sidney Clarke, Royal Botanic Garden, Edinburgh; to Mr Geoffrey Yeo, Archivist at St Bartholomew's Hospital; and to the staff of the Photographic Department at the People's Palace, Glasgow.

CORRESPONDENCE

NEUROMUSCULAR BLOCKERS IN DAY-CASE SURGERY: IS SPEED OF ONSET MORE IMPORTANT THAN DURATION OF ACTION?

Sir,—We read with interest the article by Cooper and colleagues [1] and would like to congratulate the authors. However, we believe that another perspective needs to be addressed. Cooper and colleagues and Pühringer and colleagues [2], compared intubating conditions in adults using either suxamethonium or Org 9426 (rocuronium), examining "rapid onset" and "good/excellent" intubating conditions. However, they did not focus on "rapidity of offset" of neuromuscular block, and we feel much more attention should be directed to this aspect.

In a study by Lippmann and colleagues [3], using vecuronium in a dose of 0.05 mg kg^{-1} (corresponding to the ED$_{95}$), a mean onset time of 148 s (range 90–240 s) was recorded. Although this onset time is slightly longer than that of rocuronium, it was noted that the offset time for vecuronium was only 22 min compared with the offset time for rocuronium of 30–36 min noted in other studies [1, 2]. We feel it is important to recognize that Lippmann and colleagues also achieved excellent/good intubating conditions in 95% of patients studied. Mirakhur and colleagues [4] used much smaller doses (0.1–0.2 mg kg^{-1}) than in the present study and, under these conditions, noted "satisfactory" intubating conditions in only 90% of patients, taking 90 s to achieve those conditions. Moreover, duration of action of up to 71 min was recorded, much different from that noted in the paper by Cooper and colleagues. While anaesthetic techniques differed (use of volatile agent *vs* opioids), these data would suggest that the advantage of rocuronium ultimately may be a rapid onset; however, a longer duration of action may outweigh this benefit, especially when used at the greater ED$_{95}$ dose range.

As outpatient surgery does not require rapid intubation, rapid offset of neuromuscular block is more often required. Perhaps future studies should be directed to comparing (low-dose) rocuronium with low-dose vecuronium, rather than with suxamethonium.

Sir,—Thank you for the opportunity to reply to the letter by Drs Lippmann and Ginsburg. We agree that the duration of action of vecuronium 0.05 mg kg^{-1} is shorter than that of rocuronium 0.6 mg kg^{-1}. This is not surprising because, in terms of potency, this dose of rocuronium is about twice that of vecuronium. Most other claims made by Drs Lippmann and Ginsburg, however, are not supported by the evidence they have quoted [1]. They contend that a mean onset time of 148 s for vecuronium 0.05 mg kg^{-1} is only slightly longer than that of rocuronium 0.6 mg kg^{-1}, which was about 89 s. However, not only is 148 s much longer than 89 s, but Lippmann and Ginsburg fail to point out that this time of 148 s was the time only to the start of effect of vecuronium (compared with 25.8 s for rocuronium in our study), and that the time to complete block in their study varied from 6.5 to more than 7 min, even when isoflurane was used. This time for rocuronium was 89 s. In addition, monitoring of neuromuscular block in their study did not appear to use any means of accurately measuring the block.

Excellent to good intubating conditions in 95% of patients after vecuronium 0.05 mg kg^{-1}, which they quote in their letter (assessed at what time?), appear to be a personal impression, because there are no data on intubating conditions given in the paper they have quoted [1]. They state clearly the advantage of using an agent such as vecuronium in outpatient surgery, yet fail to appreciate that, at equipotent doses, there is little difference between rocuronium and vecuronium in duration of action. Rocuronium, in addition, has the advantage of a rapid onset of action and provision of documented good intubating conditions within 60–90 s [2–4].

It appears that the effect of vecuronium had to be antagonized even after only 0.05 mg kg^{-1} was used in the study by Lippmann and colleagues [1], in which surgery lasted about 47 min. A single dose of rocuronium 0.5–0.6 mg kg^{-1} as used in recent studies would provide better relaxation for procedures of this duration and could be antagonized easily in the same way.

BLOOD LOSS DURING TOTAL HIP REPLACEMENT

Sir,—We wish to comment on the letter by Drs McSwiney, Joshi and McCaroll [1].

We reviewed 47 patients in the early 1980s who had received cemented Stanmore hip prostheses. They were anaesthetized with thiopentone, nitrous oxide, oxygen and halothane, supplemented with extradural analgesia. Systolic arterial pressure was maintained at 100 mm Hg with infusions and volatile agents.

We found that 21% (10 patients) required no blood and 47% (23 patients) did not require blood in theatre, estimated by swab weighing and suction drainage measurement.

Of the group that required no blood, the maximum decrease in haemoglobin was 2.2 g dl^{-1}, measured on the third day after operation except for one patient whose Hb decreased by 4.2 g dl^{-1} from a value of 16.0 g dl^{-1}. The decrease in haemoglobin concentration may be physiologically advantageous considering the decrease in blood viscosity.

We wish to draw attention to our reliance on the extradural technique for achieving these conditions.

N. O. Jones
J. G. Guy
Worcester Royal Infirmary
Worcester

1. McSwiney M, Joshi G, McCaroll M. Blood loss during total hip replacement. *British Journal of Anaesthesia* 1992; **69**: 331–332.

Sir,—We thank you for the opportunity to comment on the letter by Drs Jones and Guy. They state that 21% of their patients required no blood transfusion, compared with 68% of our study group. Forty-seven percent of their patients did not require transfusion during surgery, whereas no patient in our study group required such transfusion. All the patients in their study had their surgery performed under a combination of general anaesthesia supplemented with extradural analgesia; 92.5% of our group had spinal anaesthetics with only 7.5% having general anaesthesia.

The emphasis of our study was the impact of transfusion trigger guidelines on transfusion requirements for total hip replacement surgery. It would be interesting to known what criteria Drs Jones and Guy used to define the need for transfusion, as they do not appear to have reduced their transfusion requirement to the same extent.

In addition, there were no statistically significant differences in postoperative complications between our control and study groups, although the control group had a greater proportion of wound infections and thrombotic events.

METABOLIC EFFECTS OF DOBUTAMINE

Sir,—Dr Bhatt and colleagues [1] should be congratulated on their attempts at defining the relationship between oxygen consumption ($\dot{V}O_2$) and oxygen delivery ($\dot{D}O_2$) in relation to the thermogenic effect of dobutamine. We agree with the view they express that the thermogenic effects of inotropes, and thus the increased demand for oxygen and the ensuing "need" for an increase in cardiac output, has been understated in previous discussions of the $\dot{V}O_2/\dot{D}O_2$ relationship in critical illness. Their results bear out those of Ruttiman and colleagues [2] with dopamine, and our own work on the metabolic effects of both dopamine and dobutamine [3, 4]. We demonstrated an increase in energy expenditure of 33% with dobutamine at 10 μg min^{-1} kg^{-1}, compared with an increase of 24% in $\dot{V}O_2$ that they described at an infusion rate of 7.5 μg min^{-1} kg^{-1}. We found also a massive increase in circulating free fatty acid (FFA) and glycerol concentrations, and ascribed the increase in energy expenditure to increased FFA–triglyceride cycling.

Two features of the results that they presented but did not discuss further were the decrease in both noradrenaline and blood glucose concentrations. We described similar findings; the decrease in endogenous catecholamines was ascribed to the inhibitory effect of a very large increase in arterial pressure on sympathetic nervous activity, and that in blood sugar to an increase in insulin secretion, which we also demonstrated. This in turn was presumed to be attributable to the marked beta effects of the infused dobutamine.

The assertion that the increase in $\dot{V}O_2$ seen in association with an increase in cardiac output in critical illness is a result of an increase in peripheral perfusion (while the thermogenic effect of the inotropic drug used is ignored) has gone unchallenged for too long. Dr Bhatt is to be commended on bringing it to our attention.

4. Green CJ, Frazer RS, Underhill S, Maycock P, Fairhurst JA, Campbell IT. Metabolic effects of dobutamine in normal man. *Clinical Science* 1992; **82**: 77–83.

Sir,—The paper by Bhatt and colleagues [1] examined the relationship between oxygen delivery ($\dot{D}O_2$) and oxygen consumption ($\dot{V}O_2$) in healthy volunteers, on the premise that there is no tissue oxygen debt at rest in health. However, they stated that the serum lactate concentration decreased after infusion of dobutamine, and returned to the baseline value when the dobutamine was stopped. Systemic vascular resistance index (SVRI—calculated from table I) also decreased during dobutamine infusion, although mean arterial pressure increased; could this not imply an improvement in tissue perfusion with a consequent reduction in serum lactate during dobutamine infusion in healthy volunteers? As $\dot{D}O_2$ increased during the study at each infusion rate of dobutamine, the conclusion that the increase in $\dot{V}O_2$ was caused by the calorigenic effect of dobutamine cannot be inferred with certainty from the results presented. Bizouarn and colleagues [2] have shown a significant and variable difference between $\dot{V}O_2$ measurements by indirect calorimetry compared with those calculated by the Fick principle, except during cardiopulmonary bypass (CPB). Bhatt and colleagues computed $\dot{D}O_2$ from a combination of thoracic impedance plethysmography and pulse oximetry, neither of which are "gold standards", and then correlated this with $\dot{V}O_2$ measured by indirect calorimetry. The greater increase in $\dot{D}O_2$ compared with $\dot{V}O_2$ may therefore reflect differences between methods rather than a true discrepancy.

In a preliminary study (unpublished) of three patients during stable CPB at 25 °C, we have examined the effect of dobutamine infusion on VO_2 while holding DO_2 constant. Compared with a baseline before dobutamine infusion, $\dot{V}O_2$ increased by 14.8%, 17.9% and 15.7% in the three patients after 15 min of dobutamine 7.5 μg kg^{-1} min^{-1}. In two patients, $\dot{V}O_2$ had returned to the baseline value 15 min after the dobutamine was stopped (rewarming had started before the end of the 15 min in the other patient). Bhatt and colleagues may have been correct in their *assumption* that the discrepancy between $\dot{D}O_2$ and $\dot{V}O_2$ in their study indicated a calorigenic effect of dobutamine, but our results provide direct evidence for an increase in metabolic rate during dobutamine infusion.

We were puzzled by the data handling and statistics in their paper. First, the $\dot{D}O_2$ and $\dot{V}O_2$ data are presented as line graphs, implying a continuous relationship between measurement points, rather than as bar charts. As $\dot{V}O_2$ and $\dot{D}O_2$ were measured every 5 min, we wonder why the intermediate data points were not presented in the paper; it would be interesting to know how quickly the $\dot{D}O_2$ and $\dot{V}O_2$ measurements reached a plateau after each change of infusion rate. Second, in table I a decrease in serum lactate from 1.3 (SEM 0.1) to 1.2 (0.1) mmol litre^{-1} is statistically insignificant, while an increase from 1.2 (0.1) to 1.3 (0.1) mmol litre^{-1} is significant; this does not appear consistent.

The interpretation in the discussion of changes in plasma noradrenaline concentration is confusing. The results of Bhatt and colleagues in healthy volunteers (mean noradrenaline concentration 140 ng litre^{-1}) were compared with a group of patients in chronic heart failure (CHF) in whom the mean noradrenaline concentration was 518 ng litre^{-1} [3]. The CHF patients presumably suffered from down-regulation of their beta receptors. Bhatt and colleagues then quoted Sjöström and colleagues [4] to state that a decrease of 160 ng litre^{-1} in the noradrenaline concentration in the CHF patients was "metabolically insignificant", but Sjöström's group studied the effect of adrenaline infusion in healthy women and measured the plasma noradrenaline response. In any event, in Sjöström's study, infusion of adrenaline 0.01 μg kg^{-1} min^{-1} produced a 300% increase in plasma adrenaline, associated with a 14% increase in plasma noradrenaline (from 169 to 193 ng litre^{-1}) and an 8.3% increase in resting metabolic rate. Sjöström did not determine if the adrenaline or the noradrenaline was responsible for the significant increase in metabolic rate.

Sir,—We thank Drs Campbell and Green for their comments on our report. Their detailed study on the metabolic effects of dobutamine [1] had not been published at the time that our article [2] was submitted, so we were pleased to see that their results and conclusions were in close agreement with our own.

In addition to demonstrating the calorigenic effect of dobutamine, both studies showed decreases in plasma concentrations of noradrenaline and glucose. We did not speculate on the cause of the decrease in noradrenaline concentration, but would agree with their suggestion that it is caused by a reduction of sympathetic activity secondary to the increase in arterial pressure. This explanation is supported by the observation that the muscle sympathetic activity as measured by microneurography is reduced during dobutamine infusion [3].

The decrease in blood glucose concentration during dobutamine infusion would, at least in part, be explained by their finding of increased concentrations of insulin. This appears to be brought about by a beta$_2$ adrenoceptor stimulation [4]. Adrenaline causes a reduction in plasma concentrations of insulin at least during the early phase of an infusion which is probably a result of alpha$_2$ adrenoceptor stimulation [5]. As the alpha agonist activity of dobutamine is predominantly alpha$_1$ [6], the beta$_2$ adrenoceptor agonist effect becomes apparent here.

We share the view of Drs Campbell and Green that the inherent metabolic effects of catecholamines should be considered when demonstrating supply dependence of oxygen uptake or identifying "covert" tissue hypoxia.

We appreciate also the interest shown by Drs Smith, Dryden and Hume, and are sorry that they are confused by their interpretation of our paper [2]. We shall explain the many and varied points raised by them.

First, they implied that our plasma lactate concentrations were perfusion-dependent, which would presuppose that our subjects had some perfusion-limited tissue hypoxia. However, the plasma lactate concentrations of our subjects, who were young, healthy and at rest, remained within normal limits before, during and after the infusions of dobutamine. Plasma lactate concentration results from a balance between continual production and metabolism [7] and, furthermore, normal values in healthy subjects at rest do not imply perfusion-limited tissue hypoxia [8].

We are pleased that Drs Smith, Dryden and Hume are aware that $\dot{V}\mathrm{o}_2$ values calculated by the Fick principle (c$\dot{V}\mathrm{o}_2$) and those measured by indirect calorimetry (m$\dot{V}\mathrm{o}_2$) are different. They quoted the work by Bizouarn and colleagues who, with others, have recently shown that c$\dot{V}\mathrm{o}_2$ and m$\dot{V}\mathrm{o}_2$ values are not interchangeable [9–11]. Bizouarn and colleagues also listed possible causes of errors for both methods, but did not suggest or imply that measured $\dot{V}\mathrm{o}_2$ is less accurate than calculated $\dot{V}\mathrm{o}_2$. Indeed, those authors acknowledged that "the precision of the measurements (of m$\dot{V}\mathrm{o}_2$ using the Deltatrac monitor) remains satisfactory". In fact, the major criticism of studies reporting pathological dependence of $\dot{V}\mathrm{o}_2$ on $\dot{D}\mathrm{o}_2$ is the use of c$\dot{V}\mathrm{o}_2$ with its inherent flaw in mathematical coupling [12]. Measured $\dot{V}\mathrm{o}_2$ was the correct method to use in our study. The accuracy of the Deltatrac monitor has been validated [13, 14], and all the potential sources of error associated with its use [9] were absent in our study. We used a non-invasive method to measure cardiac output because we rejected the use of the thermodilution technique in awake, healthy subjects (and most, if not all, Ethics Committees would also agree). The thoracic impedance technique is not a "gold standard", but variations of 10–20% in the thermodilution measurement of cardiac output are also recognized. It was also acceptable for us to record oxygen saturation in unanaesthetized, young, healthy subjects at rest using a pulse oximeter (Sp_{O_2}). The variation in Sp_{O_2} and the oxygen saturation measured by a co-oximeter in these subjects at rest is negligible, and this has been confirmed by one of us (using the method of Bland and Altman [15]) in preparatory work for a previous study [16].

We did not assume "that the discrepancy between $\dot{D}\mathrm{o}_2$ and $\dot{V}\mathrm{o}_2$ indicated a calorigenic effect of dobutamine" (whatever that implies), as claimed by Drs Smith, Dryden and Hume. We showed an increase in $\dot{V}\mathrm{o}_2$ during infusions of dobutamine in healthy subjects at rest.

As regards "data handling and statistics", bar charts may be less confusing to Drs Smith, Dryden and Hume, but the description of our method and results clearly did not suggest "a continuous relationship between measurement points". As for intermediate data points, we did not measure $\dot{V}\mathrm{o}_2$ and $\dot{D}\mathrm{o}_2$ "every 5 min" as they had mistakenly interpreted. We used the repeated measures analysis of variance and the significance of any difference may not be apparent from the mean values alone. Part of Drs Smith, Dryden and Hume's puzzlement would be alleviated if we express the results fully rather than rounding off at a single decimal place—that is, the plasma lactate concentrations at baseline, with 2.5-, 5.0- and 7.5-μg kg^{-1} min^{-1} infusions and after infusion were 1.436 (SEM 0.085), 1.248 (0.043), 1.204 (0.045), 1.23 (0.052) and 1.348 (0.068) mmol litre^{-1}, respectively.

Drs Smith, Dryden and Hume also misinterpreted our discussion on the metabolic effects of catecholamines. We did not compare changes in noradrenaline concentration in our subjects with those reported by Collucci [17]. We put into perspective the report of Vincent and colleagues [18] that $\dot{V}\mathrm{o}_2$ was not increased after dobutamine infusion in critically ill patients without lactic acidosis; those authors cited Collucci's paper in support of their hypothesis of an attenuated endogenous catecholamine response. Drs Smith, Dryden and Hume also claimed that we quoted Sjöström and colleagues [19] "to state that a decrease of 160 ng litre^{-1} in the noradrenaline concentration in CHF patients was 'metabolically insignificant'". They must have a different edition of the Journal, as we cannot find that statement either as quoted or implied, in our edition or manuscript. We simply suggested that noradrenaline is probably a less potent calorigenic agent than adrenaline [19, 5].

Finally, Drs Smith, Dryden and Hume drew attention to their series of three patients (unpublished) in whom metabolic rate increased during dobutamine infusion. Indeed, that was also our findings and that of Green and colleagues [1] who, unknown to us, were also studying the subject at the same time.

NITROUS OXIDE ADMINISTRATION VIA OXYGEN THERAPY DEVICES

Sir,—I was interested to read the paper by Joshi, Ooi and Soni [1] on nitrous oxide administration using oxygen therapy devices. Of particular interest to me were the widely divergent results obtained when comparing the Hudson and Vickers air entrainment masks, using a flow of 50% oxygen–50% nitrous oxide (e.g. 40% mask—nitrous oxide: Hudson 6.5%, Ventimask 13.6%). I was concerned also to see that, in calculating a theoretical concentration of nitrous oxide, these workers chose to assume that altering the composition of the primary flow does not affect the entrainment ratio.

I have previously studied the Accurox air entrainment masks using a primary flow of Entonox [2]. I think it is worth noting that the nominal 35% and 50% blenders from this manufacturer provided concentrations of oxygen and nitrous oxide similar to those reported by Joshi for the Hudson 40% and Ventimask 40%, respectively.

The function of air entrainment oxygen masks is best explained by the process of constant-pressure jet mixing [3]. The equations governing B, the mass entrainment ratio (entrained mass flow: jet mass flow), are complex. However, for a given volume flow, a jet of 50% oxygen–50% nitrous oxide has a mass that is 18.75% greater than that of a jet of oxygen. Thus, even if B is unaffected by the change in primary flow, an increase in volume of entrained air of 18.75% would be predicted. My own data demonstrated an increase in entrained flow of 13% (range 5–27%) in Accurox masks. I do not accept the assumption, therefore, that altering the composition of the primary flow does not affect the entrainment ratio.

Identical masks from the same manufacturer, using either oxygen or Entonox, reliably produce the same concentrations of gases, and masks from many manufacturers, using a primary flow of 100% oxygen, provide oxygen enriched air at near specified concentrations. However, substitution of the primary flow by Entonox appears to provide quite varied concentrations of nitrous oxide and oxygen from the masks of differing manufacturers with similar nominal specifications.

I feel that the available data demonstrate an important point that is not emphasized by Joshi and colleagues. Air entrainment masks of different manufacturers cannot be relied upon to produce similar final concentrations when the primary flow is not 100% oxygen. Application of simple theoretical calculations are inappropriate and unreliable in attempting to predict the performance of these masks with a primary flow of Entonox, and the use of these masks with a primary flow other than 100% oxygen should be strongly discouraged.

Sir,—Thank you for the opportunity to reply to Dr Goddard's letter. It is unfortunate that Dr Goddard has not read our article in detail. Our study was not a theoretical analysis of the performance characteristics of simple and fixed-performance masks. The values for the likely inspired concentrations of nitrous oxide and oxygen were not derived from mathematical predictions, but were actually measured from the "trachea" of a lung model.

We agree that an assessment of the nitrous oxide–oxygen delivery characteristics of such masks requires more complex models as used by Dorrington [1] in his analysis of gas transfer in oxygen delivery systems. However, for the purpose of only checking on the general validity of our experimental results, we avoided this mathematical maze and felt that a simplified formula was adequate. Indeed, the observed variation among the various fixed-performance masks, when looking at the differences between predicted and measured concentrations of the gases in the study, strongly suggest that there were no systematic differences arising from the simplified mathematical treatment applied.

MORTALITY IN ITU PATIENTS RECEIVING NEUROMUSCULAR BLOCKING DRUGS

Sir,—Some comment has been made on the fact that no mortality figures were quoted in one of our recent papers on the use of constant infusions of atracurium in critically ill patients in an intensive care unit [1].

In this series of 15 patients, seven of whom suffered combined renal and respiratory failure and eight of whom had respiratory failure but normal renal function, the ITU mortality in the former group was 43%, and in the latter group, 25%. These mortality figures are comparable to those reported in previously published studies [2–4].

We hope that those who have made much of this omission will, in future, quote these figures directly. However, it is our belief that comparison of data on mortality, gained retrospectively, is futile because of the disparity between patients. Some form of disease classification is necessary if it is to be effective [5]. However, we would support consideration of a controlled, prospective study of mortality in the critically ill who are receiving infusions of neuromuscular blocking drugs.

FACE MASKS AND SPINAL ANAESTHESIA

Sir,—The wearing of face masks while performing spinal anaesthesia remains a controversial issue. Although there is little clear evidence for the transmission of infection to the patient during this procedure, we are reminded occasionally of the potential for serious morbidity [1]. It is therefore mandatory to consider the most appropriate way in which we can "pay attention to detail" [2] and attempt to prevent adverse events.

Philips and colleagues [3] have presented evidence to support the contention that masks are effective in reducing bacterial infection, and consequently recommended their use. However, we believe their conclusions to be flawed in one respect. They compared contamination of agar plates when subjects were talking at the plates with and without the use of a face mask. In their study, they did not examine the effect of the subject remaining mainly silent for the 5 min of the study period. If the aim is to find ways of eliminating transmission of bacteria, we feel that this aspect should be examined. It may be that remaining silent for most of the period of insertion of a spinal may itself help prevent the dispersal of upper airway organisms. Remaining mainly silent during the procedure need not compromise the anaesthetist's contact with the patient, as a full explanation of the procedure should be given before the start.

In order to examine the effect of speech on the dispersal of bacteria, we chose to simulate Philips and colleagues' study with 10 anaesthetists as subjects. The subjects were studied under three different conditions: sitting silently, 30 cm from an agar plate; sitting talking, 30 cm away from an agar plate; sitting talking and wearing a face mask, 30 cm away from an agar plate. All agar plates were incubated at 37 °C for 24 h and colonies grown were examined and counted by a microbiologist blinded to the conditions.

Our results were as follows. In group one (sitting silent) one subjects of 10 grew a total of one colony (0.1 colony/subject). In group two (talking without a face mask) five subjects of 10 grew a total of 44 colonies (4.4 colony/subject). In group three (talking with a face mask) three subjects of 10 grew a total of three colonies (0.3 colony/subject).

The large difference in numbers of colonies grown when the subject remained silent and when talking illustrates the importance of speech in the dispersal of upper airway organisms. This difference was significant at the $P < 0.01$ level when a paired Student's t test was performed. Although three times as many colonies were grown when talking while wearing a face mask compared with remaining silent without a face mask, this difference was not significant.

We suggest, therefore, that the act of speaking may itself promote the dispersal of bacteria from the upper airway, and that failing to control for this effect renders some of the conclusions of Philips and colleagues open to question. Face masks may help prevent the spread of bacteria, but our results show that remaining silent may achieve this aim at least as effectively. If the prevention of transmission of infection from the anaesthetist to the patient is paramount, then we suggest that the anaesthetist remain silent while performing spinal anaesthesia, whether a face mask is worn or otherwise.

Sir,—Thank you for the opportunity to reply to the letter from Drs O'Kelly and Marsh. Their data are interesting and valid within a specific context. However, I believe it is unrealistic to propose that an anaesthetist should remain completely silent during the course of providing a spinal or extradural block, and I would even suggest that it would be bad practice to do so. I am amazed at the contortions that some wish to go through to avoid the taking of a simple, straightforward precaution. What motives are involved I cannot understand.

PAIN ON I.V. INJECTION OF METOCLOPRAMIDE

Sir,—I was interested to read the report of Ganta and Fee [1] in which they described the use of metoclopramide 5 mg in an attempt to obtund the pain produced by induction of anaesthesia by propofol. Their work suggests that the drug is as effective for this purpose as the more commonly used lignocaine.

I have been using metoclopramide as an antiemetic for more than 2 yr. I give every patient I anaesthetize an i.v. bolus of metoclopramide 10 mg on induction, provided that there is no contraindication to its use. I have noted that if the drug is injected into a small vein on the dorsum of the hand, before any other agent, and especially in unpremedicated patients, more than 40% complain of a severe burning pain in the vein.

I believe that this response is recognized by those that use the "high dose" ampoules (100 mg) of metoclopramide in chemotherapy treatment, but not by anaesthetists. Interestingly, this side effect is not recorded in the relevant Data Sheets for this product [2]. I continue to use metoclopramide, but now administer the drug when the patient is asleep.

BOOK REVIEWS

Principles and Protocols in Intensive Care. Edited by S. M. Willatts and R. J. Winter. Published by Portland Press Ltd, Colchester. Pp. 415; indexed. Price £29.50.

This text is a 400-page, soft covered volume which is divided into 12 sections, with five appendices, covering the whole range of intensive care. All but two of the chapters have been written by the editors, which produces a very consistent approach.

The opening section provides an introduction to intensive care and includes an excellent chapter on severity scoring and outcome prediction. The subsequent sections cover the various systems of the body, with additional sections on infection, obstetrics, overdose, trauma and haematology.

The two "guest" chapters are on chest trauma and drowning and both maintain the standards set by the editors; indeed, the chapter on drowning by Dr Simcock is an excellent dissertation and should be compulsory reading for all trainees.

The appendices cover catheterization procedures, postoperative care of the cardiac surgery patient and procedures associated with organ donation. This last section is particularly well presented and will be of great value in clarifying the position for the new resident who is meeting this situation for the first time.

The editors have stated in their preface that the book is intended to fill a gap between large textbooks and brief reviews. They have achieved their intended goal with great success. This is an excellent short textbook of intensive care. It will be of great benefit to residents in the Intensive Care Unit, where it will provide useful guidelines at the bedside and, in addition, it will be an invaluable revision text for those preparing for postgraduate exams.

G. W. Jones

Conduction Blockade for Postoperative Analgesia: Mechanisms and Management. Edited by J. H. McClure and J. A. W. Wildsmith. Published by Edward Arnold, Sevenoaks. Pp. 230; indexed; illustrated.

There have recently been several new publications on postoperative pain relief, but there remains a place for a relatively short textbook dealing in depth with the role of local anaesthesia. In all respects, this book fits very nicely into the niche.

The book can be divided broadly into two sections: the pharmacology and physiology of postoperative pain treatment, and the practical aspects.

The first chapter by Cervero and Laird describes in detail the pathophysiology of pain pathways. It is an excellent up-to-date review which is difficult to criticize. It sets the scene very well for the remainder of the book and contains a particularly useful summary section. The next chapter, written by the late Ben Covino, considers the mechanisms of impulse block and reflects the true expertise of the author. It is written in a very clear and straightforward style and leaves the reader in no doubt as to the modern theories of action of the local anaesthetic agents. Neurotransmitters are clearly important in the function of pain pathways, and the next chapter considers the role of these in acute pain. Again, this is a good review, which in some respects is a logical progression from the previous chapter, but strays slightly from the purpose of the book.

As the recent report by the Royal Colleges of Anaesthetists and Surgeons makes clear, the most important reason for the treatment of postoperative pain is humanitarian. However, it is important to realize that pain has adverse effects on physiology and recovery after surgery, and the next chapter by N. B. Scott describes these. This is an awkward topic, but is covered well by the author. Again, this subject matter is a logical choice for a book of this nature, but it is not related solely to the local anaesthesia. A particular strength of this chapter is the large number of recent and well chosen references.

The remainder of the book concentrates on local anaesthetic techniques and the first chapter of this section, written by Brockway and Wildsmith, concerns intrathecal and extradural spread of drugs. The anatomy and physiology of the vertebral canal is described comprehensively and factors affecting extradural and intrathecal spread of drugs reviewed. The clinical use of spinal opioids is considered next by Morgan. Again, this is a well written and balanced review, which emphasizes the excellent analgesia that can be obtained by this method. However, the relatively high incidence of side effects is stressed, particularly respiratory depression. The relative safety of this technique compared with others is still not known for certain and he stresses the need for close monitoring of these patients. Very relevant to this last comment is the next chapter by Alfred Lee, describing the management of continuous extradural block. Management of these blocks in hospitals varies widely and it is difficult therefore to strike the correct balance in this chapter. However, the author succeeds well in giving a clear account of his subject and it is very useful indeed to those who are considering introducing extradural blocks for postoperative analgesia *de novo*.

Should a book such as this describe in great detail all known conduction blocks in anaesthetic practice? The editors have made a wise choice in describing only those procedures which are particularly suitable for providing prolonged postoperative analgesia. Thoracic and inguinal blocks and techniques for postoperative pain relief after upper and lower limb surgery are described by authors with considerable expertise in this area. Their descriptions are clear and there are many useful practical tips. In many cases, prior knowledge of the technique is assumed by the author. I believe that this is a fair and useful assumption to make, as most readers would either have seen these blocks performed or have access to a more detailed and comprehensive text.

The general layout of this small textbook is excellent. There are very many well drawn figures and the text is more than adequately referenced and indexed. I would recommend this book to all practising anaesthetists; it is a pleasure to read, and a genuine addition to the literature. If part of the function of the book is to persuade the reader to perform more local anaesthetic blocks for postoperative analgesia, then the authors have succeeded.

D. Rowbotham

Techniques in Extracorporeal Circulation, 3rd Edn. Edited by P. H. Kay. Published by Butterworth–Heinemann, Oxford. Pp. 336; indexed; illustrated. Price £95.00.

Considerable licence has been taken with the title of this book to create a compendium of modern technological aids to replace or supplement cardiac and pulmonary function. However, chapters on heart, heart–lung and lung transplantation appear incongruous, although they render the book comprehensive.

The bulk of the book comprises the many aspects of cardiopulmonary bypass and is rounded off with a set of reviews on ventricle assistance techniques, artificial hearts and respiratory gas exchange methods and devices. Each author has been given a wide brief, consequently there is much repetition of history and development, and many common themes. There is voice for designers, manufacturers and the users of cardiopulmonary bypass, but nothing from the mechanics. I feel that the perspective of a perfusionist would be valuable in reviewing their bibliography, safety measures and drills for the sudden appearance of blood clot in the reservoirs, air in the systems, and electromechanical failure.

Anaesthetists have contributed three chapters covering aspects of primes for perfusion, the cardiac anaesthetic process and intensive therapy. The first is too succinct. The second is a scratch golfer's guide to cardiac anaesthesia—straight down the fairway and no beating about the rough. The third misses an opportunity to wax lyrical on the use of chrono- and inotropes, vasodilators and constrictors with which to manipulate the post-bypass circulation; it gives no experience or imparted wisdom on interfacing patients to the technologies described in the later sections.

Some recent and current controversies are examined. The debate on neurological sequelae and complications is well aired and reaches conclusions. That on pulsatile versus non-pulsatile flow is founded and founders on evidence that is dated and based on bubble-oxygenator technology. Normothermic *vs* hypothermic bypass is broached, but is largely a subject that has arisen since the book was commissioned. What of pH *vs* alpha stat? They and it are not in the index.

With authors from both sides of the Atlantic, the usual criticisms can be levelled: there is a mixture of units of measurement, and one chapter is very difficult to read, containing malapropisms of almost presidential proportion. However, the book is really a treasure trove. To my mind, the crown jewels are chapters on filtration in bypass, intraoperative myocardial protection, neurological sequelae and intra-aortic balloon counterpulsation. They glitter, are lovingly cut, crafted, polished and assembled. There is gold also in chapters on haematology, renal failure, hypothermia and the newer technologies.

The literary line founded by Ionescue with the first edition is strong. This descendent is robust enough to maintain the health of the breed, and will probably increase in value, for it is the perfect time capsule of technology of cardiopulmonary surgery to herald the second millenium. I am tempted to hoard my copy and certainly will be circumspect with its loan or donation. I think it is a worthwhile purchase for anyone connected with this field and its fringes, for there is something of value in it for anaesthetists, surgeons, scientists or technicians, be it for interval reading, study or reference; and at a mere snip for a cardiac anaesthetist!

I. D. Conacher

Ward's Anaesthetic Equipment, 3rd Edn. By A. Davey, J. T. B. Moyle and C. S. Ward. Published by Harcourt-Brace-Jovanovich Ltd, Sidcup. Pp. 391; indexed; illustrated. Price £35.00.

This is the third edition of this textbook. Large parts of the second edition have been rewritten and revised and new material has been added. It has been revised with the needs of trainee anaesthetists in mind and the addition of two new co-authors has extended the scope of this edition. The principles that apply to the working of anaesthetic equipment and the safe use of this equipment are described.

In general, the book is well produced and illustrated. However, the medical cylinder data on the front inside cover are confusing, as the colour reproduction is poor. The bodies of the air and carbon dioxide cylinders appear green, when they should be grey.

The opening chapter covers physical principles; this has been expanded, with many useful and clear tables and graphs to explain the physical principles described. Pneumatics, fluidics and electronics are discussed in chapter 2, including brief descriptions of electronics and microprocessor systems; this is particularly relevant with the rapid expansion of microprocessor units in many types of anaesthetic monitoring equipment.

The chapter on the measurement of gas flow and volume is clear and instructive and the description of vaporizers has been updated and improved; working principles of vaporization are covered well, with many diagrams and photographs. The table of volatile anaesthetic agents should have included desflurane and sevoflurane in addition to the established agents.

Continuous flow anaesthetic machines are explained in a largely rewritten chapter, with the addition of many new photographs and diagrams. A short chapter on electronics in the anaesthetic machine has been added.

Breathing systems and their components are comprehensively covered, with descriptions of all major breathing systems, including the Humphrey ADE system. The description of the circle system has been extended and updated, with discussion of the vapour and gas concentrations produced within the system. Some parts of this chapter, particularly the descriptions of breathing attachments and face masks, remain unaltered from previous editions and have a rather old feel to them, but despite this remain useful. The description of tracheal tubes has been revised and now includes examples of the commonly used plastic tubes. The frequently used RAE tube for ENT anaesthesia is not described, and the laryngeal mask airway that has become a major influence on British anaesthetic practice over the past 5 years merits only a short description.

The chapter on resuscitation and automatic ventilators has been largely rewritten. Ventilators have been classified according to whether they are low- or high-powered and then according to the method used for cycling. The classification is then continued to cover function—mechanical thumbs, minute volume dividers and bag squeezers. Many machines are described in detail, ranging from the Cape Waine and the East Radcliffe ventilators to the Servo 900D. Description of jet ventilators has been expanded and includes a section on the Penlon Bromsgrove jet ventilator.

Chapter 14 provides an overview of the equipment used for paediatric anaesthesia; many new diagrams and photographs have been added and these are clear and instructive.

Monitoring is divided into two parts: measurement of gases used in anaesthesia and non-invasive patient monitoring. To take account of the many developments in infusion technology both in the intensive care unit and in theatre, a chapter on the basic components of infusion equipment has been added. The chapter on the psychology of accidents was both interesting and relevant.

Overall, this book has been improved considerably and updated to take account of the changes in anaesthetic practice that have occurred in the 7 years since the previous edition. This book should certainly find a place in all departmental libraries. Trainee anaesthetists preparing for the F.R.C.Anaes. examination will find it a valuable source of information and I am sure that many anaesthetists will want to add this book to their own personal library.

EXTRADURAL ABSCESS AFTER CENTRAL NEURAL BLOCK

Major sequelae, such as paraplegia and the formation of a haematoma or abscess in the vertebral canal, are extremely rare after central neural block. Because of that rarity it is essential that every case is examined in detail to see what lessons there are for others, so that the future risk of such disasters is minimized. This issue of *British Journal of Anaesthesia* contains a report of an extradural abscess that occurred in a patient who had received multiple injections of both local anaesthetic and corticosteroid drugs in the management of a chronic pain syndrome [1].

In describing this patient and referencing *selectively* a number of others from the relatively recent literature, Bromage draws our attention to the problem associated with the interval between procedure and appearance of the early symptoms and signs. This interval may be so long that not even the patient associates new developments with the previous injection, the problem being compounded if presentation is at a hospital without a record of that procedure. The index of suspicion is thus low and damage to the spinal cord or cauda equina may be irreversible before the correct diagnosis is made. It is proposed that this delay could be minimized, or even averted, if patients wear "Medic-Alert" bracelets for a period of time after performance of the block. However attractive the proposal may be at first sight, it is important to recognize that there is much that we do not know about the condition. Extradural abscess occurs sporadically in the normal population and there are no good data on its incidence, with or without prior instrumentation of the vertebral canal. There is no clear evidence to suggest a cause and effect relationship, although it is difficult to argue against this when there is a temporal connection [2]. It may also be difficult, with the benefit of hindsight, to accept or understand any delay in diagnosis, but the evidence presented indicates clearly that such delay can occur.

Against this background, it is interesting to examine the new case he describes. The first point is that the patient would appear to have received extradural injections at the mid-thoracic level, yet the abscess formed in the lower cervical region and caused a quadraplegia. Was it related to the injection? Second, it was 10 days after the last injection before persistent symptoms developed. Does it take this long for an abscess to form? Perhaps though, the relative "trauma" of the journey the patient undertook 1 week after the last injection produced a haematoma within the vertebral canal, the contents of which had been made friable by repeated injections of steroids. Such a haematoma might then have become infected and produced an abscess within 2–3 days. The final concern is that conservative treatment was continued for 4 days after a consultant neurologist made a tentative diagnosis of extradural abscess. This condition, in common with extradural haematoma, is a medical emergency that requires early diagnosis and rapid management or permanent paralysis may result, as was sadly the case here.

One would wish that a full history had elicited the background of extradural injections for a chronic pain syndrome, particularly because the patient again presented with back pain. However, the other cases that Bromage cites show that a failure to make such a connection is not an isolated occurrence. He argues that some way of heightening awareness among subsequent medical attendants is needed and thus proposes a mandatory warning system in the form of the Medic-Alert bracelet. He recognizes that there are both financial and medico–legal implications, although he makes no mention of the cost of providing a bracelet to each patient (currently £30). In the U.K. alone, many thousands of patients receive a subarachnoid or extradural injection each year and implementation would be expensive, in addition to generating significant paperwork. It would surely produce considerable patient anxiety about a complication that the great majority of anaesthetists (including frequent users of central neural block) may never see.

To disagree with the proposal does not imply that one can ignore the concerns that led Bromage to his conclusion, but a more measured approach is needed. First, we should never lose sight of the infective complications associated with our anaesthetic techniques and thus use a meticulous aseptic technique and aim to minimize local trauma. Central nerve blocks breach the very significant protection that nature provides for the central nervous system and this should never be done lightly.

Second, we need information on the incidence of extradural abscess and this requires collection of epidemiological data that include an accurate record of the number of central nerve blocks performed each year in large populations. The increasing requirement for medical audit suggests that such data may be collected more readily in future than they have been in the past. I accept that we need also to raise the index of suspicion among both patients and physicians when a patient presents with back pain sometime after a block. The difficulty in making any recommendation is that it should be based on assessment of the risk and this we do not have, and of course any recommendation has to be related to the medico–legal climate in each country. Even a manoeuvre as simple as telling the patient to remember they have received a "spinal" injection if they develop any back symptoms in the succeeding month or two may cause untold difficulties. Until we have better information, I believe that any change from current practice is almost bound to be counterproductive.

CLOSED-LOOP FEEDBACK CONTROLLED ADMINISTRATION OF ALFENTANIL DURING ALFENTANIL–NITROUS OXIDE ANAESTHESIA

H. SCHWILDEN AND H. STOECKEL

SUMMARY

We have studied the automatic administration of alfentanil during alfentanil–nitrous oxide anaesthesia in 11 patients using a closed-loop feedback control system based on EEG analysis. We chose a median EEG frequency of 2–4 Hz as the EEG set point. The slope of the asymptote to the cumulative dose requirement was used to define an effective therapeutic infusion of alfentanil. Median EEG frequency (mean (SD)) during the feedback period was 3.03 (0.45) Hz. The average effective therapeutic infusion of alfentanil was 0.140 (0.032) mg min^{-1}. We conclude that EEG feedback control may be useful in assessing and defining the dose requirements of alfentanil. (Br. J. Anaesth. 1993; **70**: 389–393)

KEY WORDS

Anaesthetic techniques: intravenous infusion, closed-loop feedback control. Analgesics: alfentanil. Brain: electroencephalogram.

In general, the continuous administration of alfentanil for maintaining general anaesthesia is supplemented by nitrous oxide, volatile or i.v. anaesthetic agents. Various methods have been used for identifying the appropriate rate of infusion to maintain an adequate level of anaesthesia. Prys-Roberts and colleagues [1] proposed the term minimal infusion rate (MIR) as that rate of infusion at which 50 % of the patients do not respond to skin incision. MIR may be considered as a systematic approach to both establishing relative potencies and providing guidelines on dosage requirements. However, by definition it requires a response to skin incision. It has been suggested that a more useful approach would be for the anaesthetist to know the rate of administration which was successful, for instance, in 95 % of patients. A potential method of defining this rate of infusion may be the use of closed-loop feedback controlled drug delivery systems.

Alfentanil decreases EEG frequency in a concentration-dependent manner [2]. The aim of this study was to identify, during alfentanil–nitrous oxide anaesthesia, the rate of infusion of alfentanil necessary to maintain a given slowing of EEG frequency.

PATIENTS AND METHODS

After obtaining institutional Ethics Committee approval and informed written consent, we studied 11 patients (ASA I, II) undergoing general surgery (table I). Premedication consisted of pethidine 50 mg and promethazine 50 mg i.m. given 45 min before anaesthesia. Anaesthesia was induced with fentanyl 0.1 mg and thiopentone 300–500 mg, followed by suxamethonium 80 mg. The trachea was intubated and the lungs ventilated with 60 % nitrous oxide in oxygen for the duration of surgery. Neuromuscular block was maintained by administration of either repetitive bolus doses of pancuronium or continuous infusion of vecuronium to maintain a 90 % reduction in twitch response to a train-of-four stimulus. Patient monitoring consisted of ECG, automatic non-invasive arterial pressure (Dinamap) and end-tidal $P\text{CO}_2$ ($P\text{E}'_{\text{CO}_2}$) (Hewlett–Packard 47210A). Artificial ventilation was adjusted to maintain $P\text{E}'_{\text{CO}_2}$ at 4.5 kPa. Immediately before skin incision, a bolus of alfentanil 3 mg was given and the feedback control system for the administration of alfentanil activated. Alfentanil was administered via an indwelling cannula in the forearm by an infusion pump (Treonic, Vickers) which was interfaced to a computer (Eltec, Eurocom). During surgery, no other anaesthetic medication was administered.

EEG analysis

Four EEG leads (Cz-Fi, Cz-Oi; i = 1,2) were amplified (Mingograph Junior, Siemens) and recorded on magnetic tape (PR 2200 Ampex). The Cz-Oi lead having the smaller impedance was used for deriving the feedback signal.

The filter settings of the EEG amplifier were 0.3 s and 70 Hz. Before A–D conversion, the signal was analogue filtered between 0.5 and 32 Hz, divided into epochs of 8.192 s and digitized at a rate of 125 Hz with 12 bit A–D resolution. Median EEG frequency of EEG power spectrum was used as feedback signal. We chose the interval 2–4 Hz as the set point for maintenance of anaesthesia [3, 4]. As the administration algorithm, we used a procedure described earlier [5–7]. This algorithm used an integrated pharmacokinetic–pharmacodynamic model to calculate the infusion strategy to set and maintain the desired effect. If measured median

EEG frequency was different from the model prediction, the model parameters were adapted appropriately. If measured median EEG frequency was outside the desired range, a new infusion strategy was derived from the adapted model to match the set point. This cycle was performed every 8.192 s.

Definition of effective therapeutic infusions

Under the condition of linear pharmacokinetics, the amount of drug administered per unit time $I(t)$ and the resulting concentration $C(t)$ is given by:

$$C(t) = \int_0^t dt' G(t-t') I(t')$$

The disposition function $G(t)$ can be modelled for alfentanil by a biexponential function [8]:

$$G(t) = A \exp(-\alpha t) + B \exp(-\beta t)$$

Assuming that the maintenance of a constant effect, E, is associated with a constant concentration, C, it can be shown [9] that the cumulative amount $D(t) = \int_0^t dt' I(t')$ to maintain E has the general form:

$$D(t) = M_1 - M_2 \exp(-kt) + I_{ss} t$$

The asymptote of the cumulative dose requirement curve, $D(t)$, is given by the function $M_1 + I_{ss} t$, where the unit I_{ss} obviously defines the slope of the asymptote. Given a feedback system which maintains a certain effect within the therapeutic window, the asymptote I_{ss} to the emerging cumulative dose curve, $D(t)$, defines an effective therapeutic infusion [7, 10]. In this study, we used non-linear least square fitting to determine I_{ss} from the foregoing formulae as an estimate of the effective therapeutic infusion of alfentanil.

RESULTS

Table II summarizes the findings of quantitative EEG analysis. According to the desired set point of median EEG frequency of 2–4 Hz, the median EEG frequency varied between individuals in the range 2.2–3.6 Hz with a mean of 3.03 (SD 0.45) Hz. As can be identified from the resolution of the power spectrum into frequency bands, EEG slowing was caused largely by a frequency shift into the frequency band of 0.5–2 Hz which contained on average 40% of total EEG power. Edge frequency (95% percentile of EEG power spectrum) was found to be 15.4 (3.1) Hz.

Figure 1 depicts the typical time course of cumulative alfentanil requirement for a typical patient (No. 1) whose effective therapeutic infusion rate was assessed as 0.14 mg min^{-1}. Figure 2 shows the time course of mean (SD) cumulative alfentanil requirement for all 11 patients for the first 120 min. The average cumulative amount for the first 120 min was 23.5 mg. Table III depicts the behaviour of arterial pressure and heart rate before anaesthesia, after skin incision and at the end of surgery and the corresponding values at greatest systolic and least diastolic arterial pressure measured during surgery. Table IV gives the individual effective therapeutic infusions for the 11 patients whose alfentanil requirements varied between 0.108 and 0.22 mg min^{-1}, and the duration of surgery and recovery time from end of surgery to opening eyes on command.

We were unable to identify a significant relationship between effective therapeutic infusion and body mass or lean body mass. None of the patients had

recall of intraoperative events on explicit questioning either immediately after extubation or 24 h after surgery.

DISCUSSION

We have demonstrated the use of EEG-driven automated feedback controlled delivery of alfentanil during alfentanil–nitrous oxide anaesthesia during surgery. Several years ago, on the basis of pharmacokinetic investigations and clinical experience [11, 12], our group proposed a target concentration of alfentanil 400–500 ng ml^{-1} during anaesthesia with 60% nitrous oxide for major surgery. Given the pharmacokinetic data of Schüttler and Stoeckel [8], this concentration corresponds to a maintenance infusion rate of approximately 0.14 mg min^{-1} for adult patients. Subsequently, several authors have undertaken studies to determine appropriate dose requirements for alfentanil, mostly in combination with 66% nitrous oxide. They usually used arterial pressure and heart rate for defining additional alfentanil requirements. Ausems, Hug and de Lange [13] reported an average rate of infusion of alfentanil 1.72 (0.15) μg kg^{-1} min^{-1} (with 66% nitrous oxide) during intra-abdominal surgery (corresponding to 0.123 (0.011) mg min^{-1} for a patient of 72 kg body weight). Lemmens and colleagues [14] reported, in a group of 18 elderly patients (65–86 yr; average body weight 67 kg), a total requirement of alfentanil 23.5 (10.7) mg for an average duration of anaesthesia of 162 (42) min (with 66% nitrous oxide); this corresponded to an infusion rate of 0.156 mg min^{-1}. Gesink-van der Veer and colleagues [15] found, in patients with Crohn's disease and of average weight 55.8 kg, a mean infusion rate of 2.1 μg kg^{-1} min^{-1} and, in a control group of average weight 64.4 kg, a mean rate of 1.05 μg kg^{-1} min^{-1}; these correspond to infusion rates of 0.151 mg min^{-1} and 0.076 mg min^{-1} for a 72-kg patient in each group, respectively.

A later study by Ausems and colleagues [16] found that an average rate of infusion of 1.43 (0.55) μg kg^{-1} min^{-1} for lower abdominal surgery and 1.99 (0.55) μg kg^{-1} min^{-1} for upper abdominal surgery (with 66% nitrous oxide) was necessary to avoid "response" as defined by a set of criteria reflecting haemodynamic and autonomic changes. These data correspond to infusion rates of 0.1 (0.04) mg min^{-1} and 0.14 (0.04) mg min^{-1} for a 72-kg patient. Comparison of these data with our study suggests that median EEG frequency may serve as an alternative guide to define appropriate doses of alfentanil during alfentanil–nitrous oxide anaesthesia. Obviously, our data do not allow us to conclude that our mode of administration is superior to repetitive bolus dosing or other infusion techniques. This requires further investigation.

This study and previous ones [5–7] confirm that feedback controlled drug delivery systems have the potential both to provide clinical anaesthesia and to serve as experimental research tools. Unlike MAC or MIR values, which use quantal responses and cannot define optimum values for achieving anaesthesia in the majority of patients, the effective therapeutic infusion concept uses a therapeutic end-point for evaluating dose requirements. The method determines not only what dose is effective in a given quantile, but also the dose that is effective in all patients.

COMPARISON OF THE EFFECT OF EMLA CREAM, SUBCUTANEOUS RING ANAESTHESIA AND A DOUBLE CUFF TECHNIQUE IN THE PREVENTION OF TOURNIQUET PAIN

Y.-C. TSAI, Y.-Y. LAI AND C.-L. CHANG

SUMMARY

*We have examined the effect of EMLA on tourniquet pain and compared it with those of subcutaneous ring anaesthesia (SRA), a double cuff technique and a single cuff (control) during i.v. regional anaesthesia. The durations of analgesia (mean 57.3 (*SD *16.6) min) and tolerance (72.3 (13.9) min) to tourniquet inflation in the EMLA group were comparable to those in the SRA group (54.1(16.2) min and 68.3(19.0) min), but significantly (*$P < 0.05$*) greater than those in the control group (30.0 (10.7) min and 45.6 (14.0) min). The double cuff technique was the most effective method, with 91.5 (14.9) min duration of analgesia. We conclude that EMLA provided a significant analgesic effect on tourniquet pain compared with the control group, but a relatively limited analgesic effect compared with a double cuff technique.* (Br. J. Anaesth. 1993; **70**: 394–396)

KEY WORDS

Anaesthetic techniques: intravenous regional. Anaesthetics local: topical lignocaine/prilocaine. Complications: tourniquet pain.

I.v. regional anaesthesia (IVRA) is a useful and safe block for analgesia of the extremities. Nevertheless, analgesia at the site of the tourniquet is not achieved as easily as that at the operative site and various methods have been described to relieve tourniquet pain [1–5]. EMLA (Astra), a 5 % eutectic mixture of two local anaesthetics, lignocaine and prilocaine, has been shown to be effective in producing local anaesthesia of intact skin in infants, children and adults [6–11]. The purpose of this study was to evaluate the effect of EMLA in the prevention of tourniquet pain, and compare it with subcutaneous ring anaesthesia (SRA), a double cuff technique and a standard technique (control).

PATIENTS AND METHODS

This study was performed in a randomized, single-blind, controlled manner and was approved by the local Ethics Committee. Informed consent was obtained from each patient. Forty adult patients (ASA physical status I or II) undergoing elective forearm or hand surgery were allocated randomly to four groups of 10. No premedication was given. With the patient supine, an i.v. cannula was placed in a vein on the dorsum of the hand or distal forearm of the limb to be blocked. The tourniquet, 6.5 cm in width, was applied midway between axilla and elbow over a cushioning layer of orthopaedic padding. Before IVRA, patients in group 1 received topically applied 5 % EMLA cream 30–35 g circumferentially over the site of the tourniquet, then an occlusive plastic dressing was positioned for 1 h. Patients in group 2 received SRA with 1 % lignocaine 20 ml, using a 22-gauge, 70-mm long needle at the site of tourniquet just before the single pneumatic tourniquet cuff was applied; the total dose of lignocaine combined with that used in IVRA was 400 mg. Double tourniquet cuffs (6 cm wide) were used in group 3 patients, without EMLA or SRA. The proximal cuff was inflated to 250 mm Hg after the arm was exsanguinated with an Esmarch bandage. The distal cuff was inflated and the proximal cuff released 30 min after i.v. injection of lignocaine. Patients in group 4 (control group) received placebo cream (a cream base containing no local anaesthetic) over the site of tourniquet, using the same procedure as in group 1. For each patient, the arm was exsanguinated by applying an Esmarch bandage from the finger tips to the tourniquet site. The cuff was inflated to 250 mm Hg. When satisfactory ischaemic conditions were obtained, the solution of 0.5 % lignocaine 40 ml was injected.

The duration of tourniquet analgesia was defined as the time between application of tourniquet pressure and complaint of tolerable pain or soreness over the tourniquet site. The duration of tourniquet tolerance was defined as the time between application of tourniquet pressure and complaint of intolerable pain or discomfort that required additional analgesia.

Data were analysed by Kruskal–Wallis test with Dunn procedure. P less than 0.05 was considered statistically significant.

RESULTS

Patient characteristics are shown in table I. The duration of analgesia to tourniquet inflation was regarded as the same as the duration of operation (which lasted longer than 90 min) if the patient still

Duration of tolerance (min)	72.3 (13.9)†	68.3 (19.0)	—	45.6 (14.0)
95% CI	(62.4–82.2)	(54.7–81.9)	—	(35.6–55.6)

had no complaint about the tourniquet site. The mean duration of analgesia to tourniquet inflation in the double cuff group was 91.5 (SD 14.9) min, which was significantly longer than that in the SRA, EMLA or control groups ($P < 0.05$) (table II). The mean duration of analgesia to tourniquet inflation in the EMLA group was 57.3 (16.6) min, comparable to that in the SRA group (54.1(16.2) min) ($P < 0.05$ compared with the control group (30.0 (10.7) min). The duration of tolerance to tourniquet inflation in the double cuff group could not be evaluated for lack of data in eight of 10 patients because surgery ended before occurrence of intolerable symptoms. The mean duration of tolerance to tourniquet inflation in the EMLA group (72.3 (13.9) min) was not significantly different from that in the SRA group (68.3 (19.0) min), but was significantly longer ($P < 0.05$) compared with the control group (45.6 (14.0) min).

DISCUSSION

To avoid subjectively reminding patients about their tourniquet pain, we did not evaluate pain scores at fixed intervals, but for practical purposes, we selected two points to evaluate pain, the duration of tourniquet analgesia and the duration of tourniquet tolerance. These two points were equivalent to each end of a visual analogue scale (perceptible and intolerable). Our study indicated that the duration of tourniquet analgesia and duration of tourniquet tolerance in the EMLA group were significantly longer compared with the control group. Lowrie, Jones and Eastley [12], studying 10 healthy male volunteers, found a significantly longer duration and smaller pain scores in an EMLA group. However, the duration of tourniquet analgesia or tolerance in the EMLA group is of little clinical significance, because the technique is time-consuming, variably effective and expensive. We found that the most reliable method was the double cuff technique.

Although the double cuff is not favoured by some users because of the increased incidence of tourniquet failure in IVRA [13, 14], this technique is both effective and safe in the prevention of tourniquet pain if used correctly and carefully. Brown, McGriff and Malinowski reviewed 1906 cases receiving IVRA with a double tourniquet and concluded that the major cause of adverse effects was technical error [15]. It is essential that all equipment be checked before use. However, it is held by many clinicians that the double cuff method is less safe than a single cuff technique. Using EMLA cream or SRA to prevent tourniquet pain with a single cuff technique may be an alternative, but not ideal, method in clinical practice.

Subcutaneous ring anaesthesia was reported by Rousso and colleagues to be an excellent analgesic technique for tourniquets [2]. However, in our study, SRA only provided similar analgesia as EMLA. Lack of a control group and the duration of observation in Rousso's study may explain the difference in observations. Although there were no toxic signs in the SRA group patients who received lignocaine 400 mg (half in SRA and half in IVRA), the total dose was significantly in excess of the maximal recommended doses. However, the recommendation of a single maximum dose without regard to the site of injection is of little significance [16]. The plasma concentration of local anaesthetic drugs varies considerably as a function of the site of injection [17]. To achieve a plasma toxic concentration of lignocaine administered by subcutaneous infiltration requires a much greater dose than administration via the intercostal, extradural or brachial plexus routes [18]. Nevertheless, we did not measure serum concentrations of lignocaine in the SRA group.

The mechanism of tourniquet pain has been the subject of much debate [1, 12, 19–21]. Many factors are thought to be implicated. Cole [19] suggested that tourniquet pain had both a superficial and a deep component. Rousso and colleagues [2] and Lowrie, Jones and Eastley [12] proposed that tourniquet pain has a significant cutaneous component. In our study, EMLA and SRA provided predominantly superficial analgesia, and both provided only limited analgesia, suggesting that skin compression is one component of tourniquet pain.

The double cuff technique prevents tourniquet pain by the same mechanism as that of IVRA. The site of action of IVRA is controversial, but is explained best by multiple and complementary mechanisms [22–24]. With 0.5% lignocaine 40 ml in IVRA, the double cuff tourniquet can provide more reliable anagesia at the tourniquet site.

ACKNOWLEDGEMENT

We thank Astra Pharmaceuticals for supplying the EMLA cream.

COMPARISON OF *IN VITRO* CONTRACTURE TESTING WITH RYANODINE, HALOTHANE AND CAFFEINE IN MALIGNANT HYPERTHERMIA AND OTHER NEUROMUSCULAR DISORDERS

P. M. HOPKINS, F. R. ELLIS AND P. J. HALSALL

SUMMARY

In vitro *exposure of living skeletal muscle to ryanodine has been proposed as a potentially specific test for malignant hyperthermia (MH). In this study we have compared* in vitro *contracture responses to halothane, caffeine and ryanodine in skeletal muscle specimens obtained from 155 patients attending for diagnosis of susceptibility of MH and also from six patients having muscle biopsy for diagnosis of other neuromuscular disorders. Although the ryanodine contracture test was not specific for MH, the results suggest it may greatly aid (in conjunction with the standard halothane and caffeine contracture tests) the accurate phenotyping of individuals that is essential for the further genetic analysis of MH.* (Br. J. Anaesth. 1993; **70**: 397–401)

KEY WORDS

Hyperthermia; malignant, in vitro *test. Pharmacology: ryanodine.*

Both of the two widely used procedures for the diagnosis of malignant hyperthermia (MH) susceptibility using *in vitro* contracture tests (IVCT) with living skeletal muscle [1, 2] use separate exposure to halothane and to caffeine. The regimen of the North American MH Group also allows for a combined caffeine–halothane test [2], but recently this has been invalidated because of a high incidence of false positive results [3, 4]. The separate-exposure halothane and caffeine tests also have imperfections. Results of IVCT performed in patients with a low risk of MH ("controls") suggest a false positive rate of approximately 4 % using the European procedure [5] and 9 % using the North American procedure [3]. In our series of more than 2400 tests, 14 % of patients with an abnormal response to halothane reacted normally to caffeine, indicating the caffeine test lacks total sensitivity. Both procedures are associated also with lack of specificity, in that muscle from patients with myopathies other than MHS develop abnormal contracture responses [6, 7]. It was for these reasons, and with the need for the most accurate phenotyping of MH susceptibility for successful genetic analysis of the condition, that we investigated the potential of the plant alkaloid, ryanodine, for use in IVCT. The early results of our ryanodine contracture test were encouraging and were presented as a preliminary report [8].

We now present results from 155 patients attending for diagnosis of their MH status, on whose muscle IVCT have been done using halothane, caffeine and ryanodine. In a similar way, we also investigated muscle specimens from six patients with other neuromuscular disorders.

PATIENTS AND METHODS

Patients attending for investigation of MH status

Muscle specimens were obtained by open biopsy of the vastus medialis under regional anaesthesia (3 in 1 block) or general anaesthesia (thiopentone, fentanyl and nitrous oxide in oxygen) and maintained and used for diagnostic IVCT according to the European MH Group procedure [1]. MH status was assigned in the usual way using suitably viable specimens (twitch response > 1 g): abnormal responses to halothane (> 0.2 g contracture with $\leqslant 2\,\%$ halothane) and caffeine (> 0.2 g contracture with caffeine $\leqslant 2$ mmol litre^{-1}) indicates MH susceptible (MHS); abnormal response to only one of either halothane or caffeine indicates MH equivocal (MHE); normal responses to both drugs indicate non-susceptibility (MHN). Any muscle fascicle surplus to diagnostic requirements was used for a ryanodine contracture test (RCT). The first 63 of these were performed as described previously [8] with ryanodine added in increments at 3-min intervals to achieve muscle bath concentrations of 0.4, 0.8, 1.6 and 10 μmol litre^{-1} (RCT version 1). For the remaining 92 patients, additional ryanodine concentrations of 3.2 and 6.4 μmol litre^{-1} were included (RCT version 2). The RCT was modified in an attempt to produce a clear distinction in ryanodine threshold *concentration* between MHS and MHN groups. Initially, the threshold value of ryanodine was determined as that concentration of ryanodine at which a contracture of 0.2 g developed. This was soon changed to the concentration of ryanodine at which a sustained contracture commenced. The results presented here use this later definition for threshold value of ryanodine. For

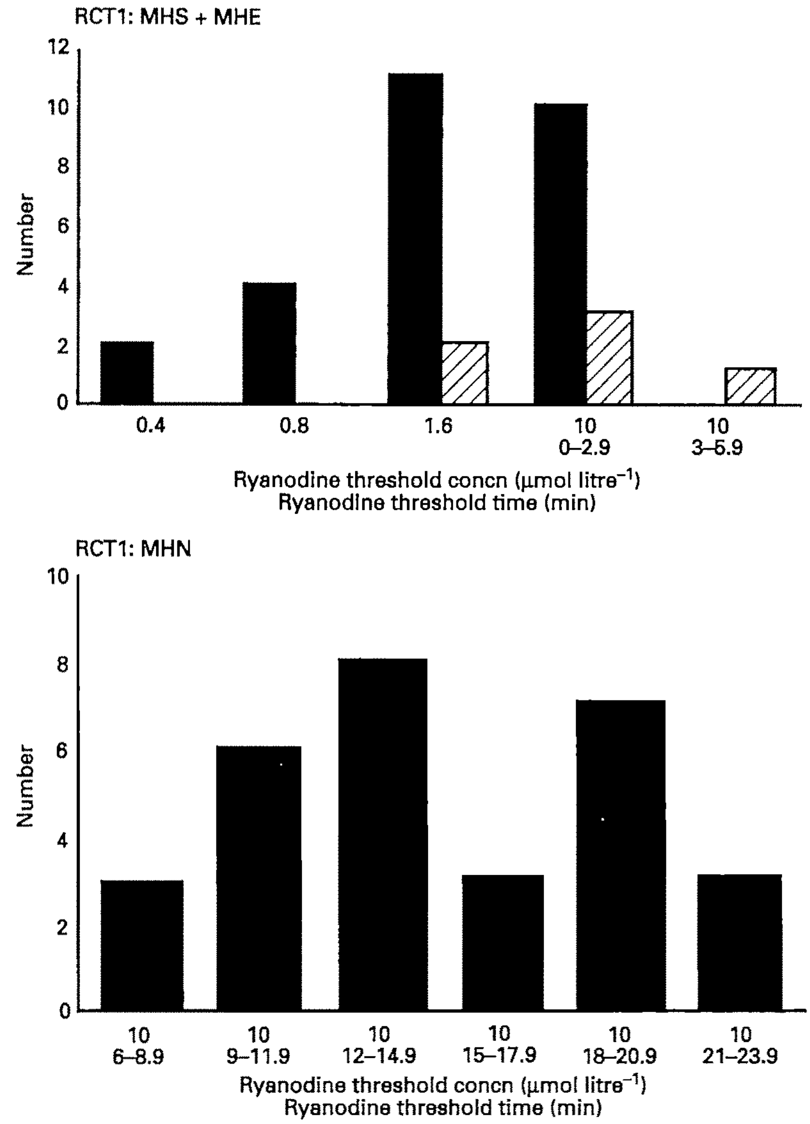

FIG. 1. Ryanodine thresholds using RCT version 1 for MHS (■) and MHE (▨) patients and for MHN patients. Ryanodine was added in increments at 3-min intervals to achieve muscle bath concentrations of 0.4, 0.8, 1.6 and 10 µmol litre^{-1}. The threshold value of ryanodine was determined as that concentration of ryanodine at which a sustained contracture commenced. If no contracture had developed within 3 min of exposure to ryanodine 10 µmol litre^{-1}, this concentration was maintained until a contracture did develop and the contracture threshold expressed as the time (in minutes) after exposure to ryanodine 10 µmol litre^{-1}.

version 1 of the RCT, where no contracture had developed within 3 min of exposure to ryanodine 10 µmol litre^{-1}, this concentration was maintained until a contracture did develop and the contracture threshold expressed as the time (in minutes) after exposure to ryanodine 10 µmol litre^{-1}.

Patients with other neuromuscular disorders

Six patients attending for muscle biopsy for histological diagnosis of a clinical neuromuscular disease were included. Surplus tissue was used for halothane, caffeine and ryanodine contracture tests that were performed as for the MH patients.

The ryanodine used (ryanodine dehydroryanodine, 98% pure) was obtained from Agri Systems Chemicals (Philadelphia, U.S.A.).

RESULTS

Patients attending for investigation of MH status

RCT version 1 (fig. 1). Of the 63 patients investigated, 27 were classified as MHS, 30 as MHN and six as MHE. All the MHS muscle fascicles developed a contracture within 3 min of exposure to the greatest concentration of ryanodine (10 µmol litre^{-1}). No MHN fascicle developed a contracture by this stage, the earliest contractures occurring after 7 min of ryanodine 10 µmol litre^{-1}. The MHE fascicles had lower thresholds than the MHN fascicles.

RCT version 2. Results of the RCT version 2 of 26 MHS, 52 MHN and 14 MHE patients are shown in figure 2. The one MHS fascicle with a ryanodine

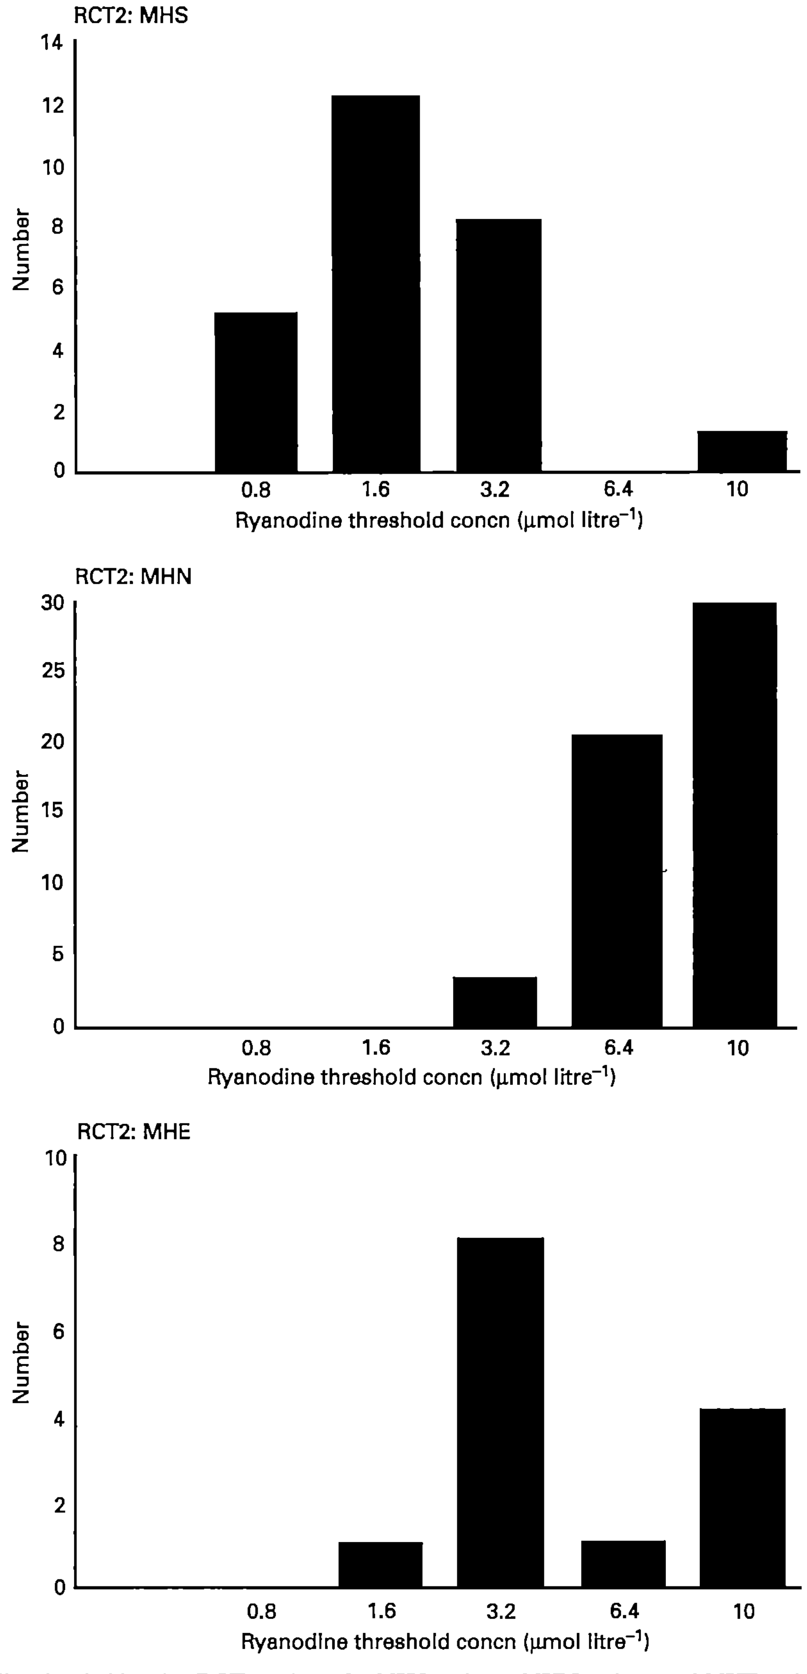

FIG. 2. Ryanodine thresholds using RCT version 2 for MHS patients, MHN patients and MHE patients. Ryanodine was added in increments at 3-min intervals to achieve muscle bath concentrations of 0.4, 0.8, 1.6, 3.2, 6.4 and 10 μmol litre^{-1}. The threshold value of ryanodine was determined as that concentration of ryanodine at which a sustained contracture commenced.

TABLE I. *Results of halothane, caffeine and ryanodine (version 2) contracture tests in individual MHE patients. Halothane test; threshold concentration of halothane and maximum force of contracture obtained at 2% halothane in the static test; DH = abnormal response to only the dynamic halothane test. For description of static and dynamic tests see [1]. * Poorly viable specimen (twitch response < 1 g), the result from which should be interpreted with caution*

	Halothane		Threshold concentration	
MHE	Threshold concn (%)	Maximum contracture (g)	Caffeine (mmol litre^{-1})	Ryanodine (μmol litre^{-1})
1	0.5	1	3	3.2
2	1	2.1	3	1.6
3	1	1.3	3	3.2
4	1	1.3	3	3.2
5	1	0.9	3	3.2
6	2	0.6	3	3.2
7	2	0.4	3	6.4
8	2	0.2	3	3.2
9	2	0.2	3	3.2
10	2	0.2	4	3.2
11	2	0.2	4	10*
12	2	0.2	> 4	10
13	1	DH	4	10
14	2	DH	> 4	10*

threshold greater than 3.2 μmol litre^{-1} was poorly viable (twitch response = 0.1 g). The halothane, caffeine and ryanodine thresholds for the important group of patients classified as MHE are shown in table I. The relationships between the thresholds in individual patients for halothane, caffeine and ryanodine (version 2) contracture tests (HCT, CCT and RCT respectively), as indicated by the Spearman rank correlation coefficient (rs) were: HCT *vs* RCT, rs = 0.737 ($P < 0.001$); CCT *vs* RCT, rs = 0.736 ($P < 0.001$); HCT *vs* CCT, rs = 0.787 ($P < 0.001$).

Patients with other neuromuscular disorders

Histological diagnosis and details of results of halothane, caffeine and ryanodine contracture tests are shown in table II. There was insufficient muscle for a caffeine contracture test in one patient.

DISCUSSION

The results of the diagnostic investigations for MH susceptibility in the 155 patients studied here are typical for our laboratory, with 34% classified as MHS, 13% MHE and 53% MHN. When the European MH Group procedure was agreed, there was a consensus that it was far more important, from a clinical perspective, to avoid false negative rather than false positive diagnoses. As one of the purposes of this process was to enable validation of results and research between European laboratories, it was necessary to set criteria for recognition of true MH positive and true MH negative patients that became, respectively, the MHS and MHN categories. It was perhaps unfortunate, and the cause of considerable confusion since, that those patients not meeting the criteria for MHS or MHN were labelled "equivocal". While this group of patients, probably, does include those with false positive results (true equivocals), the European Group's study of low risk patients indicated a false positive rate of about 4% [5]. This suggests that the majority of the MHE patients are susceptible to MH. In our laboratory, all MHE patients respond abnormally to halothane and it is our contention that this large MHE group is, therefore, a reflection of the lack of sensitivity of the caeffeine contracture test rather than a lack of specificity of the halothane contracture test. It should be noted, however, that in some centres MHE status results from an abnormal caffeine response with normal halothane response.

However, these points were only of academic importance with respect to the original goals of the European MH Group. Clinically, MHE patients usually were (and still are) regarded as susceptible to MH, but only MHS and MHN patients are entered in research programmes. Since 1984 there have been major and rapid advances in the field of molecular biology that have resulted in the real prospect of identifying the gene defect(s) responsible for MH. The nature of the required linkage studies was described elegantly by Levitt and colleagues [9], but the critical point is that their accuracy is dependent

TABLE II. *Halothane, caffeine and ryanodine contracture test results in six patients with various neuromuscular disorders. RCT version 1 was used for patients Nos 1–4; RCT version 2 used for patients Nos 5 and 6. The threshold value of ryanodine was determined as that concentration of ryanodine at which a sustained contracture commenced. If no contracture had developed within 3 min of exposure to ryanodine 10 μmol litre^{-1}, this concentration was maintained until a contracture did develop and the contracture threshold expressed as the time (in minutes) after exposure to ryanodine* 10 *μmol litre^{-1}*

		Contracture (g)			
				Ryanodine threshold	
Patient No.	Diagnosis	Halothane (force at 2%)	Caffeine (force at 2 mmol litre^{-1})	Concn (μmol litre^{-1})	Time (min)
1	Motor neurone	0.15	0	10	4
2	Facioscapulohumeral dystrophy	0.1	0.4	10	2
3	Type IIb fibre atrophy	0.2	0.1	10	5
4	Acute myositis	0.4	—	10	7
5	Acute denervation	0	0	3.2	—
6	Polymyositis	0	0	6.4	—

entirely on the accurate phenotyping of as many individuals as possible from MH families by IVCT. For these studies it is essential, therefore, that the numbers of false positive, false negative and doubtful IVCT diagnoses are minimized. To achieve this, it is clear that the MHE classification must be redressed.

Experience with the European MH Group procedure has demonstrated that positive results in two distinct tests increase the statistical confidence of the diagnosis of susceptibility to MH. This principle logically might be extended by the addition of a third test. Examination of the results obtained using RCT version 2 indicates that this warrants consideration for use as such a third test. If a ryanodine threshold of 3.2 μmol litre^{-1} or less is taken as an abnormal result, the RCT successfully identified the MHS patients (excluding the result obtained with poorly viable muscle). Furthermore, if one assumes that the MHN group are true negatives (which is highly likely), the RCT has a false positive rate of 5.8% (99% confidence interval of −2.5% to 14.1%). The most exciting aspect of the RCT, however, is that it appears to identify two populations within the MHE group, which suggests it does have the potential to distinguish positive and negative patients within this group. From this study, it is possible to conclude the following about individual MHE patients: a ryanodine threshold of 1.6 μmol litre^{-1} indicates MH susceptibility with near certainty; a ryanodine threshold of 3.2 μmol litre^{-1} indicates a probability of at least 85% of MH susceptibility; a ryanodine threshold of 10 μmol litre^{-1} indicates almost certainly non-susceptibility to MH. Although no MHS patient (with viable specimen) had a ryanodine threshold greater than 3.2 μmol litre^{-1}, an insufficient number of MHS patients has been studied to permit the conclusion that MHE patients with a ryanodine threshold of 6.4 μmol litre^{-1} are not susceptible. However, the lower limit of the 99% confidence interval for the probability that patients with a ryanodine threshold of 6.4 μmol litre^{-1} are not susceptible is 83%.

MacKenzie and colleagues [10] have suggested that the threshold force of contracture for the halothane contracture test is too low. From the results shown in table I, it can be seen that it would be unwise to increase the threshold force of contracture at 2% halothane to more than 0.2 g as, of the five patients with muscle reaching no greater force, three had a ryanodine threshold of 3.2 μmol litre^{-1}, while one had a normal response to ryanodine (threshold of 10 μmol litre^{-1}). The specimen from the fifth such patient for the RCT was poorly viable. Of course, if must be noted that the RCT may be unreliable with poorly viable specimens and we would recommend that, as stipulated in the European MH Group procedure for halothane and caeffeine tests, muscle specimens must have a twitch response of at least 1 g.

The IVCT results from muscle of patients with other neuromuscular disorders (table II) confirm earlier studies [6, 7] which demonstrated that neither halothane or caffeine contracture tests are specific for MH. The present results also show that the RCT is also not specific for MH. That the most abnormal response with the RCT was seen in denervated muscle suggests the RCT is able to detect some forms of diseased muscle (primary and secondary conditions), rather than only those caused by an abnormal ryanodine receptor protein (sarcoplasmic reticulum calcium release channel). Results of the RCT, therefore, are consistent with the hypothesis that MH is caused by an abnormal ryanodine receptor protein gene [11, 12], but equally consistent with MH being a genetically heterogeneous condition [13].

ACKNOWLEDGEMENT

We thank Mr P. L. Allam and Ms A. Clough for technical assistance.

RECOVERIES OF POST-TETANIC TWITCH AND TRAIN-OF-FOUR RESPONSES AFTER ADMINISTRATION OF VECURONIUM WITH DIFFERENT INHALATION ANAESTHETICS AND NEUROLEPTANAESTHESIA

Y. SAITOH, H. TOYOOKA AND K. AMAHA

SUMMARY

We have studied recovery of post-tetanic twitch (PTT) and train-of-four (TOF) responses after administration of vecuronium in 100 patients under different inhalation anaesthetics and neuroleptanaesthesia. Patients were allocated randomly to five groups of 20 patients each to receive: neuroleptanaesthesia (droperidol and fentanyl), halothane, isoflurane, enflurane or sevoflurane (1 MAC in nitrous oxide and oxygen). The times from initial administration of vecuronium 0.2 mg kg^{-1} to the first appearances of T1, T2, T3 and T4 differed significantly between groups. However, the intervals to the first appearance of PTT$_1$, PTT$_{10}$ and PTT$_{20}$ did not differ significantly between groups. (Br. J. Anaesth. 1993; **70**: 402–404)

KEY WORDS

Monitoring: post-tetanic-twitch, train-of-four. Neuromuscular relaxants: vecuronium.

Post-tetanic twitch (PTT) is a valuable method for evaluating intense neuromuscular block, because PTT response can be observed earlier than train-of-four (TOF) response during recovery of neuromuscular transmission after non-depolarizing neuromuscular blocking agents [1–3]. Recovery of TOF or single twitch responses under different types of anaesthesia has been studied by several authors [4–8], but recovery of PTT responses has not been reported. We have studied the intervals between initial administration of vecuronium to the first appearances of PTT$_1$, PTT$_{10}$, PTT$_{20}$, T1, T2, T3 and T4 with different inhalation anaesthetics and neuroleptanaesthesia, and evaluated the use of PTT in assessing the degree of neuromuscular block.

PATIENTS AND METHODS

With institutional Review Board approval and written informed consent, we studied 100 adult patients (53 male), ASA class I or II, undergoing elective general surgical, orthopaedic, gynaecological, urological, ENT or ophthalmological procedures. None of the patients had neuromuscular, renal or hepatic disorders or received any medication that might alter neuromuscular transmission. They were allocated randomly to five groups of 20 patients each to receive: neuroleptanaesthesia (NLA group), halothane (group H), isoflurane (group I), enflurane (group E) or sevoflurane (group S). All the patients were premedicated with atropine 0.01 mg kg^{-1} and hydroxyzine 1 mg kg^{-1} i.m. 1 h before operation. Stimulating surface electrodes were placed on the ulnar nerve at the elbow and recording electrodes on the corresponding abductor digiti minimi muscle. After induction of anaesthesia with sodium thiamylal 5 mg kg^{-1}, the ulnar nerve was stimulated supramaximally (50 mA) with an electrical stimulator (SEN-3201, Nihon-Kohden Inc., Tokyo). Rectangular pulses of 0.1 ms duration were triggered automatically by a computer to produce two patterns of electrical stimulation (TOF and PTT) as described below. When the response to TOF stimulation was stable, the magnitude of the first twitch of the train was taken as the control twitch height. Vecuronium 0.2 mg kg^{-1} i.v. was then administered to facilitate tracheal intubation. Anaesthesia was maintained with 66 % nitrous oxide in oxygen and fentanyl 5 μg kg^{-1} and droperidol 0.2 mg kg^{-1} in the NLA group. In the other groups, anaesthesia was maintained with 66 % nitrous oxide in oxygen and 1 MAC end-tidal inhalation anaesthetic (0.76 % halothane, 1.15 % isoflurane, 1.68 % enflurane or 1.71 % sevoflurane). The end-tidal concentrations of carbon dioxide, nitrous oxide, and inhalation anaesthetics were measured by infra-red absorption using a Capnomac Ultima-S-31-03 (Datex Inc., Helsinki) calibrated with standard gases. Patient's lungs were ventilated to normocapnia as measured by end-tidal carbon dioxide and intermittent arterial blood-gas analysis. Rectal temperature was maintained at 35.5–36.8 °C with warming blankets. During the first 5 min after a control measurement was obtained, TOF stimuli were applied every 5 s to monitor relaxation for tracheal intubation. Five minutes after a control measurement was obtained, the intervals between TOF stimuli were changed to

T4	58.18 (12.07)	58.31 (10.12)	64.80 (9.20)	69.60 (13.64)**	70.91 (10.88)**

30 s and PTT stimuli were substituted for TOF stimuli every 150 s. This pattern of stimulation was continued until the end of anaesthesia; thereafter, 100 % oxygen was given to the patients and atropine 1 mg and neostigmine 2 mg i.v. were given to antagonize any residual neuromuscular block.

For TOF stimulation, a series of four pulses was applied at 2 Hz for 2 s. For PTT, a tetanic stimulus (50 Hz) was applied for 5 s and, after an interval of 3 s, single twitch stimuli (1 Hz) were applied for 20 s. The EMG response of each stimulus was amplified via an isolated differential amplifier (AVB-11, Nihon-Kohden Inc., Tokyo) and displayed on an oscilloscope (VC-11, Nihon-Kohden Inc., Tokyo). These EMG signals were then gated (gate open from 3 to 25 ms after test stimuli) to reduce the stimulation artefact, rectified and integrated for each single response, using a specially designed integrator with reset and sample hold circuit, by digital commands from a computer. Integrated data sets of either TOF or PTT responses were displayed on a monitoring oscilloscope and stored on hard disc. A personal desk-top computer (PC-9801 UX, NEC Inc., Tokyo) was used for overall control of automatic stimulation–data collection sequences, and for later data analysis. The intervals from initial administration of vecuronium to first appearance of PTT_1, PTT_{10}, PTT_{20}, T1, T2, T3 and T4 were calculated. The responses to electrical stimuli were considered to be detectable when the magnitudes were larger or equal to 1 % of control.

Statistical analysis was performed using ANOVA and Duncan's multiple range test [9] to test for differences between the five groups, $P < 0.01$ being considered significant. All results are expressed as mean (SD).

RESULTS

There were no significant differences in patient characteristics between the five groups (table I).

The interval to the first appearances of PTT_1, PTT_{10} and PTT_{20} did not differ significantly between the five groups (table II).

The intervals to the first appearances of T1, T2, T3 and T4 in groups E and S differed significantly from those in the NLA group and group H. However, those in group I were not significantly different from those in the four other groups (table III).

DISCUSSION

Recovery of post-tetanic twitch is a valuable indicator for evaluating intense neuromuscular block produced by non-depolarizing neuromuscular blocking agents, because the appearance of PTT responses can be observed earlier than TOF responses during the recovery of neuromuscular transmission [1–3].

Baker and colleagues [10] and Riker [11] reported that PTT was a sensitive index of neuromuscular block produced by non-depolarizing neuromuscular blocking agents at the prejunctional region (motor nerve endings); however, twitch heights of TOF in comparison with control twitch height are affected by postjunctional effects [12, 13]. It is known also that inhalation anaesthetics act mainly in the postjunctional region of the neuromuscular junction and prolong the duration of neuromuscular block produced by non-depolarizing neuromuscular blocking agents to varying degrees [4, 5, 12, 14, 15]. Kennedy and Galindo [14] reported that enflurane reinforced the muscle twitch depression produced by tubocurarine in the rat phrenic nerve–diaphragm preparation and that it was caused primarily by the postjunctional effect. Gissen, Karis and Nastuk [15] showed, in the frog sciatic nerve–sartorius muscle, that the structure most sensitive to the neuromuscular blocking action of halothane is the postjunctional membrane. Thus the inhalation anaesthetics prolong the duration of neuromuscular block produced by non-depolarizing neuromuscular blocking agents, by acting mainly at the postjunctional membrane. Therefore it is not surprising that the appearance of PTT, an index of prejunctional block, did not differ between our five groups, whereas the appearance of T1–T4, an index of postjunctional block, differed significantly between the groups. We found that, in ranking order, sevoflurane, enflurane, isoflurane and halothane prolonged the intervals to the first appearance of T1–T4. This is in agreement with previous studies [4–8].

There was little difference in the first appearances of T1–T4 between the NLA group and group H. Bonsu and colleagues [1] found that the interval from the first appearance of PTT_1 to that of T1 was 9 min with halothane anaesthesia, and 10 min with fentanyl anaesthesia after administration of atracurium 0.6 mg kg^{-1}; the difference was not significant.

Itagaki and colleagues [4], Miller and colleagues [16] and Vitez and colleagues [17] reported that halothane increased blood flow in skeletal muscle to a smaller extent than that caused by other inhalation anaesthetics. This may explain partly why halothane apparently did not prolong the duration of neuromuscular block. As isoflurane takes 90 min [18] and enflurane takes 200–240 min [19] to reach the neuromuscular junction in effective concentrations, and because the end-tidal concentration of inhalation anaesthetics may not equilibrate with inspired concentrations until at least 20 min after commencement of administration [20, 21], we may have underestimated the prolongation of vecuronium-induced neuromuscular block by the inhalation anaesthetics.

It is possible that relatively short interval (2.5 min) between stimuli with PTT may have influenced recovery of neuromuscular transmission in the arm investigated [22]. We used this interval because of the relatively rapid recovery from neuromuscular block produced by vecuronium, but this problem may require further investigation. Moreover, the interval between stimuli with TOF during the induction of anaesthesia (5 s) may have been too short. This pattern of stimulation was used in order to determine the appropriate moment for smooth tracheal intubation. However, the interval was changed subsequently to 30 s and this duration would have little influence, if any, on subsequent evaluation of the neuromuscular block [23].

PREJUNCTIONAL ACTION OF NEOSTIGMINE ON MOUSE NEUROMUSCULAR PREPARATIONS

M. F. M. BRAGA, E. G. ROWAN, A. L. HARVEY AND W. C. BOWMAN

SUMMARY

We have studied the effects of neostigmine on the mouse diaphragm and triangularis sterni isolated nerve–muscle preparations. Mechanical responses of the muscle, end-plate potentials and miniature end-plate potentials, and extracellularly recorded nerve ending currents were recorded. In the mouse diaphragm nerve–muscle preparations, neostigmine 1 µmol litre^{-1} *continued to produce some antagonism of tubocurarine-induced block after cholinesterase had been inactivated completely by di-isopropyl fluorophosphate 22 µmol litre*$^{-1}$*. In the mouse triangularis sterni preparation, neostigmine 0.1–1 µmol litre*$^{-1}$ *increased the quantal content of the end-plate potential in a concentration-dependent manner. This effect appeared to be sufficient to account for the cholinesterase-independent antagonistic action to tubocurarine under the conditions of the experiments. Neostigmine 1–100 µmol litre*$^{-1}$ *depressed the amplitude of the* K^+ *currents of the perineural waveforms in a concentration-dependent manner, and this may account for its ability to increase the quantal content of the end-plate potential. Although inhibition of acetylcholinesterase is the main mechanism of action of neostigmine, the drug also exerts an additional direct action on motor nerve endings to block the delayed rectifier* K^+ *channels and enhance transmitter release. This effect occurred at clinically relevant concentrations of neostigmine. Physostigmine and pyridostigmine did not possess this additional action.* (Br. J. Anaesth. 1993; **70**: 405–410)

KEY WORDS

Antagonists: neostigmine. Neuromuscular function: acetylcholine release.

Neostigmine is an anticholinesterase agent used to antagonize neuromuscular block produced by non-depolarizing blocking drugs. While neostigmine undoubtedly inhibits the acetylcholinesterase of the neuromuscular junction, it is not certain if this is the only mechanism whereby it facilitates transmission at this site [for reviews of the literature see 1–3]. It has been suggested that, in addition to inhibiting cholinesterases, the drug acts directly on post-junctional acetylcholine receptors [4–7] or acts on the nerve endings to increase the quantal content of the end-plate potential [8], possibly by increasing the number of functional release sites [9]. In large concentrations, the drug may impair neuromuscular transmission by occluding the acetylcholine receptor-operated ion channels [10].

In the experiments described in this paper, we have studied the effects of neostigmine on the mouse diaphragm and triangularis sterni isolated nerve–muscle preparations in an attempt to elucidate the complex actions of this drug at the neuromuscular junction. In particular, we have studied the effects of small concentrations of neostigmine which should be clinically relevant. We have measured mechanical responses of diaphragm preparations to direct electrical stimulation and to nerve stimulation in order to distinguish between possible effects on neuromuscular transmission and on muscle contractility. Intracellular recordings were made from muscle end-plate regions; by comparing effects on end-plate potentials (EPP) evoked by nerve stimulation and on spontaneously occurring miniature end-plate potentials (MEPP), actions on the quantal release of acetylcholine can be determined. Extracellularly recorded nerve ending currents (perineural waveforms) have been recorded in order to reveal possible effects of neostigmine on ion channels in motor nerves.

MATERIALS AND METHODS

Mouse diaphragm nerve–muscle preparations

We dissected phrenic nerve–hemidiaphragm preparations from 15–25 g male mice (Balb C strain) killed by exsanguination after cervical dislocation. The preparations were mounted in 10-ml tissue baths containing physiological salt solution of the following composition (mmol litre^{-1}): NaCl, 118.4; KCl, 4.7; $MgSO_4$, 1.2; KH_2PO_4, 1.2; $CaCl_2$, 2.5; $NaHCO_3$, 25; glucose, 11.1. The solution was maintained at pH 7.3 and bubbled with oxygen containing 5% carbon dioxide. Experiments were carried out at room temperature (20–25 °C). The phrenic nerve was stimulated at frequencies of 0.1 or

Correspondence to W.C.B.

0.05 Hz with rectangular pulses of 0.2 ms duration and of a strength greater than that required to produce maximal twitches. In addition, the muscle was stimulated directly at a frequency of 0.05 Hz with rectangular pulses of 2 ms duration and strength greater than that required to produce maximal twitches. Twitches were recorded isometrically on Grass 79B and Washington ink writing polygraphs using Grass FT03 or SRI force transducers.

We studied the effects of neostigmine on neurally evoked twitches after a 70% reduction in twitch amplitude had been produced by tubocurarine 0.2–2.0 μmol $litre^{-1}$ or by physiological salt solution containing low Ca^{2+} (0.5 mmol $litre^{-1}$) and high Mg^{2+} (2.5–5.0 mmol $litre^{-1}$). The latter conditions were used to reduce acetylcholine release in an attempt to reveal possible presynaptic actions of neostigmine. In some experiments, neostigmine was tested during partial block produced by α-bungarotoxin and also on directly evoked twitches after neuromuscular transmission had been abolished by α-bungarotoxin. In these experiments, the concentrations of neostigmine were increased cumulatively when the twitch height had stabilized after the previous addition. In other experiments, partial paralysis was induced by tubocurarine and antagonized by the organophosphate anticholinesterase di-isopropyl fluorophosphate (DFP). Additional tubocurarine was given to re-establish a partial block, and antagonism was attempted with DFP, neostigmine, physostigmine or pyridostigmine.

Mouse triangularis sterni preparations

Experiments were performed at room temperature (20–25 °C). The left triangularis sterni nerve–muscle preparation [11] was isolated from 15–25 g male mice (Balb C strain). During dissection, the muscle with its three nerves was perfused continuously with the physiological salt solution described above. The preparation was pinned thoracic side downwards to the base of a 3-ml tissue bath and perfused at a rate of 5–10 ml min^{-1} with the physiological salt solution described above, to which tubocurarine 10 μmol $litre^{-1}$ (for extracellular recording) or Mg^{2+} 2–5 mmol $litre^{-1}$ (for intracellular recording) was added to prevent muscle twitching. In all Mg^{2+}-paralysed preparations, the Ca^{2+} concentration was reduced to 0.5 mmol $litre^{-1}$ and 20 min allowed for equilibration. The intercostal nerves were stimulated via a suction electrode every 2 s with pulses of 50 μs duration and supramaximal strength.

Intracellular recording. Neuromuscular junctions were identified by the presence of EPP and MEPP with rise times of 1 ms or less. EPP and MEPP were recorded using glass microelectrodes filled with potassium chloride 3 mol $litre^{-1}$ (resistance 5–20 MΩ), as described previously [12]. Neostigmine was added cumulatively (from 0.1 to 10 μmol $litre^{-1}$) and the concentration of neostigmine was increased when its effect on EPP amplitude and time course had stabilized after previous addition of the drugs. Recordings were made continuously from one end-plate area before and throughout application of drugs. The potentials were recorded, amplified and stored as described previously [12]. The time constants of decay of EPP and MEPP were measured in order to quantify the prolongation of action of acetylcholine in the presence of an anticholinesterase. Quantal content (the average number of packets of acetylcholine released in response to nerve stimulation) was determined by dividing the mean amplitude of EPP by the mean amplitude of MEPP recorded from the same site.

Extracellular recording. Presynaptic waveforms generated by nerve action potentials were recorded by a glass microelectrode (filled with sodium chloride 2 mol $litre^{-1}$, resistance 5–15 MΩ) placed inside the perineural sheath (near end-plate areas) of one of the branches of an intercostal nerve [13–15]. The potentials were recorded, amplified and stored as for the intracellular recordings. Usually, 20 to 25 waveforms were recorded at each time period. As the shape of the waveform recorded is dependent on the electrode position, waveforms were monitored continuously from the same site before and throughout application of drugs. Recording sites were rejected if the signal amplitude decreased by more than 10% during the first 20 min before the addition of the compounds. Using this design, stable recordings could be obtained over a 180-min period in control solutions or in the presence of drugs.

Materials

All the compounds were obtained from Sigma Chemical Co., Poole, Dorset.

Analysis and statistics

The recording system had an overall passband of d.c.-10 kHz and signals were digitized at 25 kHz, which was more than twice the filter cut off frequency (Nyquist criteria). The signals were analysed with a suite of purpose-designed programs [16] running on an IBM-compatible microcomputer (Vanilla, 286-12A).

Values in the text are mean (SE) of at least four experiments, unless stated otherwise. Differences between means were tested using the Mann–Whitney *U* test, $P < 0.05$ being taken as significant.

RESULTS

Mouse diaphragm nerve–muscle preparations

Neostigmine antagonized a 70% reduction of indirectly elicited twitch height induced by tubocurarine 0.2–2 μmol $litre^{-1}$. Complete antagonism of tubocurarine paralysis was produced with neostigmine 0.1 μmol $litre^{-1}$, and in the presence of greater concentrations (1–10 μmol $litre^{-1}$), augmentation of the maximal twitches from control was induced, presumably because the action of acetylcholine was prolonged sufficiently to induce repetitive muscle action potentials and consequent tetanic contractions (fig. 1). However, neostigmine only partially antagonized the 70% reduction in indirectly elicited twitch height induced by physiological salt solution containing Ca^{2+} 0.5 mmol $litre^{-1}$ and Mg^{2+} 2.5–5 mmol $litre^{-1}$. The threshold concentration was 0.1 μmol $litre^{-1}$ and the maximum recovery was about 72% (fig. 1). In contrast, neostigmine

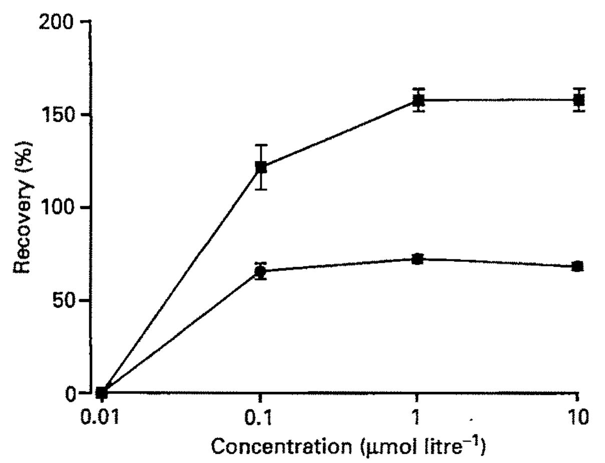

FIG. 1. Antagonism of tubocurarine block by neostigmine (■), and antagonism of low Ca^{2+}–high Mg^{2+} block by neostigmine (●): responses of mouse hemidiaphragm nerve–muscle preparations to indirect muscle stimulation once every 10 s. Experiments were carried out at room temperature (20–25 °C). Points are means of four experiments, and SE are indicated by the bars unless smaller than symbols.

1–10 μmol $litre^{-1}$ failed to antagonize the block induced by α-bungarotoxin 500 nmol $litre^{-1}$ (an irreversible blocker of nicotinic cholinoceptors) or to increase directly elicited twitch height when neuromuscular transmission was blocked completely by α-bungarotoxin 500 nmol $litre^{-1}$ (fig. 2).

In order to investigate if neostigmine has any facilitatory effects on neuromuscular transmission independent of its anticholinesterase activity, experiments were carried out in which a 70 % block of indirectly elicited twitch height induced by tubocurarine 0.2–2 μmol $litre^{-1}$ was antagonized completely by DFP 22 μmol $litre^{-1}$. (DFP is an irreversibly acting organophosphate anticholinesterase agent.) Then, a subsequent addition of tubocurarine 0.3–1 μmol $litre^{-1}$ was used in order to induce a 70 % block of indirectly elicited twitch height. Under these conditions, addition of DFP 11 μmol $litre^{-1}$ failed to increase twitch height. However, addition of neostigmine 1 μmol $litre^{-1}$ produced a further increase in twitch height of 37 (4) % ($n = 4$) (fig. 3). Physostigmine 0.1–10 μmol $litre^{-1}$ and pyridostigmine 0.1–10 μmol $litre^{-1}$, when tested under the same conditions, did not produce further increase in twitch height; for example with 3 μmol $litre^{-1}$, twitch height with physostigmine and pyridostigmine remained at 102 (7) % ($n = 4$) and 96 (8) % ($n = 4$), respectively, of the partially blocked values. The greatest concentrations of both compounds (10 μmol $litre^{-1}$) caused a reduction in twitch height (data not shown).

Mouse triangularis sterni nerve–muscle preparations

Intracellular recording. In Mg^{2+}-paralysed preparations, control MEPP were 0.32–0.71 mV in amplitude and had a time constant of decay of 1.5–2.1 ms. The EPP were 1.1–3.5 mV in amplitude and had a time constant of decay of 1.3–2.2 ms at a resting membrane potential of −65 to −85 mV. Neostigmine 0.1–1 μmol $litre^{-1}$ increased quantal content (fig. 4A). For example, quantal content was increased by 20 (6) % ($n = 3$) and by 79 (28) % ($n = 4$) by neostigmine 0.1 and 1.0 mmol $litre^{-1}$, respectively (fig. 4A). However, in the presence of greater concentrations of neostigmine (3–10 μmol $litre^{-1}$), the quantal content was reduced towards control values (fig. 4A). As would be expected with an anticholinesterase, neostigmine 0.1–1 μmol $litre^{-1}$ also increased the time constant of decay of the MEPP and EPP in a concentration-dependent manner, until the time course was about 200 % of control (fig. 4A, B). With greater concentrations of neostigmine (3–10 μmol $litre^{-1}$), the increase in the time constant of decay was less pronounced (fig. 4A, B). In addition, neostigmine 0.1–1 μmol $litre^{-1}$ increased EPP and MEPP amplitude (fig. 4A, B). However, greater concentrations of neostigmine (3–10 μmol $litre^{-1}$) reduced the amplitude of MEPP and of EPP to values less than control (fig. 4A, B).

Extracellular recording. The perineural waveform is composed predominantly of two negative deflections, usually preceded by a small positivity as the action potential arrives near the nerve endings.

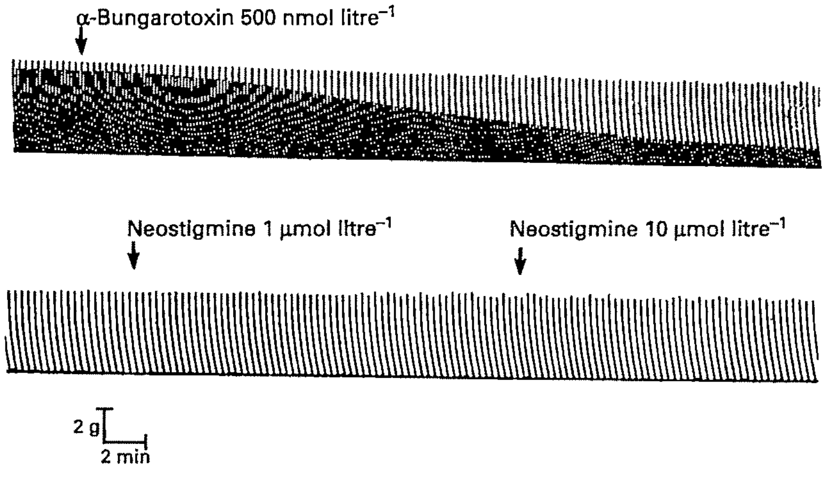

FIG. 2. Indirectly elicited (smaller traces) and directly elicited (larger traces) twitches of an isolated phrenic nerve–hemidiaphragm preparation. Indirectly elicited twitches were blocked by α-bungarotoxin 500 nmol $litre^{-1}$. Neostigmine 1–10 μmol $litre^{-1}$ failed to increase the directly elicited twitch height or to antagonize the α-bungarotoxin-induced neuromuscular paralysis. Experiments were carried out at room temperature (20–25 °C). Preparations were stimulated once every 10 s.

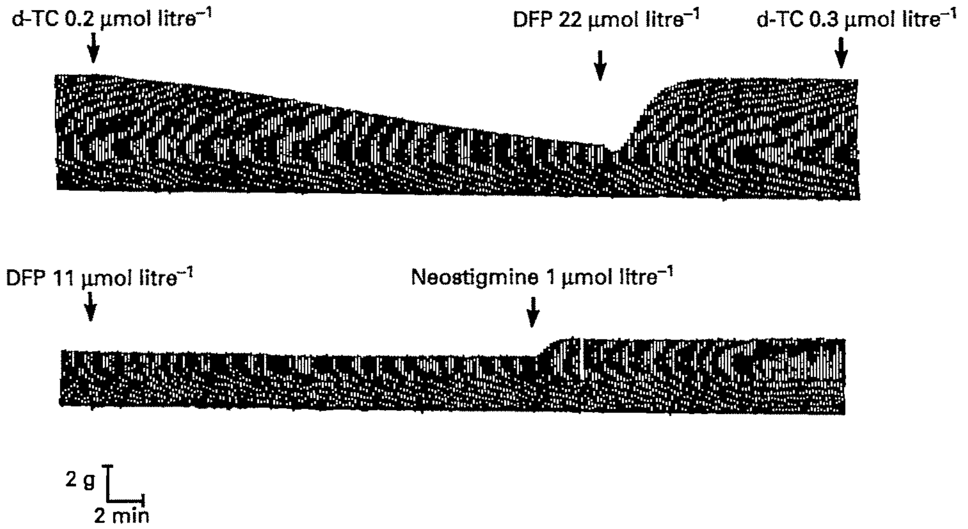

FIG. 3. Isolated phrenic nerve–hemidiaphgram preparation. Antagonism by DFP 22 μmol litre^{-1} of a 70% block of indirectly elicited twitch height induced by tubocurarine (d-TC) 0.2 μmol litre^{-1}. Then, a subsequent addition of tubocurarine 0.3 μmol litre^{-1} was used in order to induce, again, a 70% block of indirectly elicited twitch height. Under these conditions, a subsequent addition of DFP 11 μmol litre^{-1} failed to increase twitch height but the addition of neostigmine 1 μmol litre^{-1} could induce a further increase in twitch height. Experiments were carried out at room temperature (20–25 °C). Preparations were stimulated once every 10 s. Note that there is a 23-min gap in the recordings shown in the figure between the upper and lower panels.

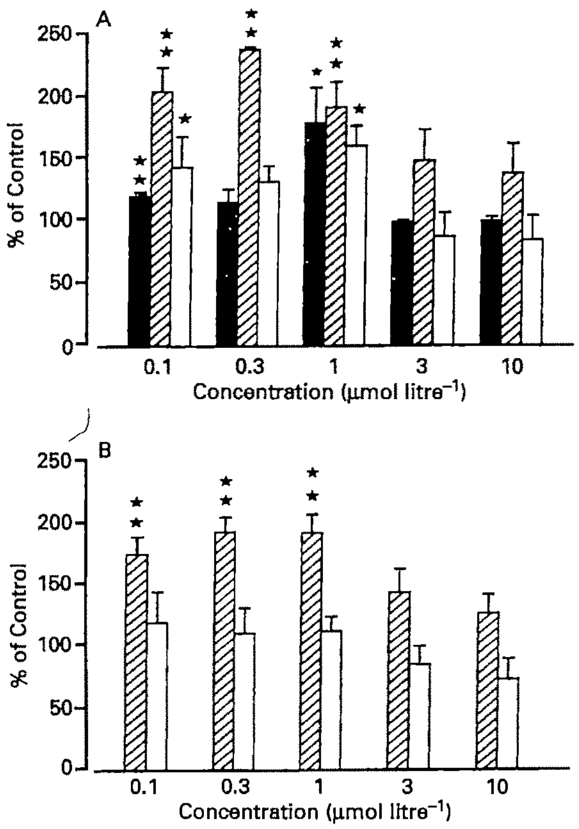

FIG. 4. A: Effects of neostigmine on EPP amplitude (□), time constant of decay (▨) and mean quantal content (■). B: Effects of neostigmine on MEPP amplitude (□), time constant of decay (▨). Columns represent means from 3–4 experiments on mouse triangularis sterni preparations; SE are shown by vertical bars. Significantly different from control: $^*P < 0.05$; $^{**}P < 0.01$.

The first negative deflection is associated with the inward movement of Na$^+$ ions at the nodes of Ranvier and heminode. The second negative deflection is the sum of the currents associated with the local circuit generated by outward movement of K$^+$ and the inward movement of Ca^{2+} at the nerve terminals (fig. 5A) [13, 14, 17]. Neostigmine 1–400 μmol litre^{-1} induced a concentration-dependent reduction in the second negative deflection of the perineural waveform, but had little or no effect on the first negative spike (fig. 5B). Similar effects with neostigmine were observed in the presence of a Ca^{2+}-free salt solution (fig. 5C).

DISCUSSION

Neostigmine is a powerful anticholinesterase and there is no reason to suppose that this is not the main basis of its facilitatory action on neuromuscular transmission. However, the present experiments show that it exerts an additional contributory action, albeit of lesser importance. Thus, in the presence of large concentrations of DFP which produced maximal antagonism of tubocurarine and which were therefore assumed to have produced maximal inhibition of junctional acetylcholinesterase, neostigmine continued to produce a further anticurare effect. Under these conditions, physostigmine and pyridostigmine failed to produce further antagonism of tubocurarine, suggesting that they do not share the extra action possessed by neostigmine. The action of neostigmine was clearly exerted on the transmission mechanism, because it had no effect on muscle contractions evoked by direct muscle stimulation.

Neostigmine produced the well documented increase in amplitude and duration of EPP and MEPP which are largely explicable in terms of its inhibitory action on acetylcholinesterase, as its ability to interact directly with postjunctional acetylcholine receptors requires very large concentrations [4–7]. In addition, the drug increased the quantal content of the EPP, which is attributed to an increase in

AN ALTERNATIVE METHOD OF INCREASING $P\text{CO}_2$ USING APNOEA AND CONTINUOUS POSITIVE AIRWAY PRESSURE

R. KARLSTEN AND S. ENGLESSON

SUMMARY

We have examined the use of continuous positive airway pressure (CPAP) and apnoeic oxygenation for restoration of spontaneous breathing at the end of anaesthesia after controlled ventilation. We studied 45 adult patients without a history of acute or chronic respiratory disturbances. Anaesthesia was induced with thiopentone or propofol and maintained with nitrous oxide and enflurane in oxygen. The patients were normocapnic during artificial ventilation. At the end of surgery, the lungs were ventilated for 5 min with oxygen and then given a CPAP of 8 cm H_2O. *Spontaneous ventilation was regained after a mean of 5 min and an arterial blood sample was obtained at the third breath. All patients were well oxygenated (*$P\text{O}_2$ *mean 43.5 kPa, range 21–76 kPa) when spontaneous ventilation started. The pH was close to 7.28 in most cases (mean 7.28, range 7.21–7.32), and* $P\text{CO}_2$ *varied in the range 6.6–9.9 kPa (mean 7.9 kPa). It is concluded that the method is safe with regard to oxygenation and acid–base balance.* (Br. J. Anaesth. 1993; **70**: 411–413)

KEY WORDS

Anaesthetic techniques: controlled ventilation, Ventilation: apnoeic oxygenation, CPAP.

At the end of general anaesthesia with artificial ventilation, spontaneous ventilation must be restored. During surgery, there is often a tendency to overventilate the lungs [1]. In order to stimulate spontaneous ventilation, three principal different methods have been used to increase $P\text{CO}_2$ at the end of anaesthesia [2]: to increase $P\text{CO}_2$ by decreasing alveolar ventilation; to bypass the soda-lime and depend on the metabolically produced carbon dioxide; and to supply exogenous carbon dioxide.

We have examined an alternative method of increasing arterial $P\text{CO}_2$ to greater than the apnoeic threshold in anaesthetized patients who have undergone normoventilation during surgery. The principle was to maintain oxygenation by apnoeic mass movement oxygenation [3] and continuous positive airway pressure (CPAP) and allow the patients themselves to restore $P\text{CO}_2$ to greater than the apnoeic threshold. The aim of the study was to evaluate the safety of this method with regard to oxygenation and acid–base balance and to determine the Pa_{CO_2} and pH at which spontaneous ventilation is regained after enflurane anaesthesia. We also intended to compare potential differences between patients in whom anaesthesia was induced with propofol and those given thiopentone.

PATIENTS AND METHODS

The study was approved by the Hospital Ethics Committee. Forty-five patients (25 male), mean age 39.9 yr (range 18–73 yr), without acute or chronic respiratory disturbances, undergoing elective ENT surgery under general anaesthesia, gave informed consent to participate in the study. They received our standard premedication with Ketogan (ketobemidone 5 mg and N,N-dimethyl-3,3-diphenyl-1-methylallylamine chloride 25 mg ml^{-1}) 0.5–1 ml and atropine 0.5 mg (patients younger than 65 yr) or glycopyrronium 0.2 mg (patients older than 65 yr) i.m.

The patients were allocated randomly to induction of general anaesthesia with propofol ($n = 19$) or thiopentone ($n = 26$) i.v., after which anaesthesia was maintained with 70% nitrous oxide and 1–2% enflurane. Fentanyl 0.05–0.1 mg was given at induction and supplementary doses (0.05–0.1 mg) were administered when needed. The total dose of fentanyl administered was 0–0.2 mg (mean 0.07 mg). Neuromuscular block was initiated with suxamethonium or vecuronium–pancuronium and if needed, maintained with incremental doses. Neuromuscular block was monitored using a peripheral nerve stimulator (Organon, Peripheral Nerve Stimulator, Neuro Technology, Houston, U.S.A.). Before insertion of the tracheal tube, the larynx and upper trachea were anaesthetized with 4% lignocaine solution. After intubation, the lungs were ventilated with an Excessobag anaesthesia ventilator (a bag-in-box device with a time-controlled injector) using a co-axial breathing system, with the same performance as the Bain [4]. The lungs were ventilated with a tidal volume of 0.01 litre kg^{-1} and a frequency of 12 b.p.m. with 0.1 litre kg^{-1} min^{-1} fresh gas flow during the first 10 min, reducing to 0.07 litre

TABLE I. *Arterial blood-gas tensions 25 min after adjustment of fresh gas flow to 70 ml kg^{-1} min^{-1} (mean (SD)).* n = 20

pH	$P\text{CO}_2$ (kPa)	$P\text{O}_2$ (kPa)	HCO_3 (mmol litre^{-1})	Base excess (mmol litre^{-1})
7.39 (0.04)	5.64 (0.60)	18.2 (6.0)	25.3 (1.9)	0.67 (2.1)

kg^{-1} min^{-1}. Oxygenation was monitored with pulse oximetry (Ohmeda, Biox 3740, Pulse Oximeter, Louisville, U.S.A.). In the first 20 patients (nine given propofol and 11 thiopentone), an arterial blood sample was obtained 25 min after the fresh gas flow was adjusted to 0.1 litre kg^{-1} min^{-1}. At the end of surgery, after antagonism of neuromuscular block, the lungs were ventilated with 100% oxygen for 5 min with a fresh gas flow 1 litre min^{-1} less than the sum of nitrous oxide in oxygen used during anaesthesia, to eliminate most of the nitrous oxide. Thereafter, the ventilator was set at CPAP 8 cm H_2O. When spontaneous breathing began, an arterial blood sample was obtained at the third breath and analysed for blood-gas tensions and acid–base state, at the gas laboratory of the Department of Clinical Physiology using an ABL II blood-gas machine (Radiometer, Copenhagen)

Statistics

All results are presented as means (SD). Statistical evaluation was performed using Student's *t* test. Linear regression was analysed for the relationship between Pa_{CO_2} and pH against the duration of apnoea.

RESULTS

Anaesthesia lasted between 45 min and 2 h 15 min. During surgery and at restoration of spontaneous breathing, there was no difference in Pa_{O_2}, Pa_{CO_2} or pH between the patients who received propofol, compared with those given thiopentone. Consequently, the results in all patients are presented together in tables I and II.

During anaesthesia, mean pH was 7.39 (SD 0.04) and Pa_{CO_2} 5.6 (0.6) kPa (table I).

The mean Pa_{CO_2} at which spontaneous ventilation was regained was 7.9 (0.8) kPa and the pH was 7.28 (0.02); all patients had increased Pa_{O_2} (43.5 (13.5) kPa (range 21–76 kPa)). The mean time for apnoea and CPAP was 5 (2.2) min.

The correlation between Pa_{CO_2} and pH *vs.* duration of apnoea is presented in figure 1.

DISCUSSION

At the end of general anaesthesia with artificial ventilation there are three major methods of allowing resumption of spontaneous breathing [2]: to let the patient regain consciousness, which may restart spontaneous breathing at a value of $P\text{CO}_2$ less than the apnoeic threshold [1, 2, 5]; to increase $P\text{CO}_2$ to greater than the apnoeic threshold [1, 2]; and to administer a non-specific stimulant [2].

One possible disadvantage with the first of these methods is that, after tracheal extubation, the patient might hypoventilate when left unstimulated, as in the recovery room [6]. The influence of external stimulation was reported in an early study by Utting and Gray [7], in which no respiratory depressant drugs were used and breathing resumed at decreased $P\text{CO}_2$. They concluded that stimuli arising from the periphery were sufficient to cause initiation of breathing. They also reported that, if topical analgesia had been applied to the larynx and trachea before intubation, there was frequently a delay in resumption of spontaneous ventilation.

It is inevitable that, after operation, $P\text{CO}_2$ increases to greater than the apnoeic threshold [2]. If the patient is allowed to breathe air after operation, there is a risk of hypoxaemia when the patient hypoventilates in order to refill the carbon dioxide stores [8]. Even if supplementary oxygen is delivered, hypoventilation may cause atelectasis, with hypoxaemia in the later postoperative period. For these reasons, it seems sensible to increase the $P\text{CO}_2$ at the end of anaesthesia.

There are also three methods of increasing $P\text{CO}_2$ to greater than apnoeic threshold [1, 2]. The first is to decrease alveolar ventilation at the end of surgery [1, 2]. This is a slow method and has the added risk of hypoxaemia because of alveolar hypoventilation and development of alveolar collapse [1]. The second method is to cause rebreathing of carbon dioxide by removing the soda-lime canister. This method is a little faster than the first [2]. The third and quickest method is to add carbon dioxide gas to the breathing system [1, 2]. This increases $P\text{CO}_2$ to the desired value in less than 1 min [1]. However, the addition of a carbon dioxide flowmeter to the system introduces several hazards. Death and permanent cerebral damage have been reported secondary to accidental high flows of carbon dioxide gas [9, 10].

Our method of increasing $P\text{CO}_2$ by using apnoea and CPAP induced spontaneous breathing in all patients while the Pa_{O_2} was well within safe margins. Emergence was smooth, as spontaneous breathing was restored and the trachea extubated before full consciousness was regained. With modern postoperative care there is usually no reason to waken the patient fully in the operating theatre, and it may be preferable to allow the patient to regain consciousness slowly in the postoperative ward. Because $P\text{CO}_2$ has been increased to greater than the apnoeic threshold, this may reduce the risk of hypoventilation during transport from operating

theatre and in the postoperative ward. However, Salvatore, Sullivan and Papper have shown that, if the lungs have been hyperventilated during surgery (the duration of the hyperventilation averaged 2.75 h), this might not be true, as the patients are depleted of body stores of carbon dioxide and have a deficit of carbon dioxide even after apnoea [8]. Recovery from such depletion is achieved by relative hypoventilation in the first 1 h after operation, with consequent risk of hypoxaemia [8, 11]. Even if supplementary oxygen is administered during this period, relative hypoventilation may induce atelectasis. For this reason, it seems sensible not to hyperventilate the lungs during anaesthesia.

In three of our patients, apnoea lasted 9–9.5 min and breathing started at a pH of 7.21–7.24 (fig. 1). All three patients had a low frequency of ventilation (4–5 b.p.m.) and their pupils were small, indicating opioid effects. These effects were antagonized easily with naloxone.

Severe hypercapnia is not necessarily fatal, provided adequate oxygenation is maintained [12, 13]. However, a long duration of apnoea might indicate that the patient is suffering from respiratory depression. This observation has led us to set a limit on the duration of apnoea as 8 min, after which we look for causes of respiratory depression (fig. 1).

Edelist and Osorio [14] have shown that the drive to resume ventilation in passively hyperventilated dogs and humans is the result of restoration of CSF pH to normal even though the blood is well oxygenated, extremely alkalotic and hypocapnic. In addition, it takes time to establish equilibrium between blood and brain PCO_2, and therefore it is difficult to extrapolate from blood PCO_2 to the actual respiratory centre pH [15]. For this reason, the results in the present study should not be thought of as "respiratory threshold values". Frumin, Epstein and Cohen [16] showed that severe respiratory acidosis (without hypoxia) produced by apnoea lasting more than 30 min could be tolerated easily by lightly anaesthetized normal patients, with complete recovery. That study also indicated that the serum concentration of potassium did not change markedly during apnoea. Holmdahl [3] studied the effects of 6 min of apnoeic diffusion oxygenation and found that all patients remained well oxygenated and that pH decreased by 0.14–0.18.

VENTILATORY EFFECTS OF MORPHINE, PETHIDINE AND METHADONE IN CHILDREN

K. HAMUNEN

SUMMARY

The ventilatory effects of single i.v. doses of morphine 0.1 mg kg^{-1}, pethidine 0.67 mg kg^{-1} and methadone 0.1 mg kg^{-1} were compared after ophthalmic surgery in an open, randomized study in 30 children aged 3–8 yr. Ventilatory changes after each drug had distinctive profiles, with appreciable individual variation. Acutely, the decrease in ventilatory frequency was greater with pethidine and methadone than with morphine. The acute decrease in oxygen saturation was greater with methadone and pethidine than with morphine. Methadone produced a greater and longer lasting increase in end-tidal carbon dioxide and greater decrease in end-tidal oxygen than morphine or pethidine. Changes in end-tidal carbon dioxide and oxygen concentrations and saturation were most transient after pethidine and of longest duration after methadone. No child developed apnoea or hypoventilation requiring assistance. (Br. J. Anaesth. 1993; **70**: 414–418)

KEY WORDS

Anaesthesia: paediatric. Analgesics: methadone, morphine, pethidine. Pain: postoperative.

Depression of ventilation is an inevitable effect of all mu receptor agonists. The principal mechanism involves decreased responsiveness of the respiratory centres to increases in carbon dioxide tension. Nevertheless, because of technical difficulties and ethical issues, only a few paediatric studies on the ventilatory effects of i.v. opioids have been carried out. Morphine is an opioid fundamental to the treatment of pain in both children and adults, and a standard drug against which other analgesics are compared in clinical trials. When given for pain, morphine rarely causes clinically important ventilatory depression in children [1–3], although ventilatory frequency is decreased in both children and adults [4, 5]. Pethidine is used often in the management of paediatric pain and premedication, even though it has few, if any, documented advantages over morphine. The analgesic efficacy and side effects of pethidine are comparable to those of morphine, but it has a shorter duration of action [6]. During recent years, methadone has been advocated for management of postoperative pain, and in some countries it is fundamental to the treatment of cancer pain in children [7]. The analgesic effect of methadone is comparable to that of morphine, but of considerably longer duration [8–12].

Analysis of end-tidal gases is a non-invasive, continuous and sensitive method of measurement of the ventilatory variables [13, 14]. The aim of this study was to compare the effects of equianalgesic i.v. single doses of morphine hydrochloride (referred to subsequently as morphine), pethidine and methadone given after operation, on ventilatory frequency, end-tidal carbon dioxide and oxygen concentrations and peripheral arteriolar oxygen saturation in children.

PATIENTS AND METHODS

The study was an open, randomized, single-dose design approved by the local Ethics Committee. Parental informed consent was obtained for all children. Children were excluded if they had severe cardiovascular or respiratory disease, hepatic or renal insufficiency, any congenital or genetic disorder possibly causing atypical opioid response or kinetics, or were severely overweight.

We studied 30 children aged 3–10 yr, undergoing elective ophthalmic surgery. Patients were allocated to groups according to the day of birth (1–10 days of month morphine, 11–20 days pethidine and 21–30 methadone). Premedication comprised oral liquid flunitrazepam 0.1 mg kg^{-1} (maximum 2 mg). Anaesthesia was induced with thiopentone 5 mg kg^{-1}. Patients were intubated and ventilated to normocapnia using a Siemens–Elema 900 ventilator (Siemens, Sweden). Anaesthesia was maintained with 66% nitrous oxide and 1–2 vol% halothane in oxygen. Relaxation was produced with pancuronium and the degree of block was monitored with a transcutaneous nerve stimulator. At the end of surgery, residual neuromuscular block was antagonized with neostigmine and glycopyrronium. No analgesics were given during anaesthesia.

After transfer to the recovery room, patients were given additional oxygen for 20 min. Non-invasive arterial pressure measurement, ECG (for heart rate) and pulse oximetry (peripheral arteriolar oxygen

saturation, Sp_{O_2}) were monitored using a Cardiocap CMO (Datex, Helsinki, Finland). End-tidal carbon dioxide (E'_{CO_2}) and oxygen (E'_{O_2}) concentrations and ventilatory frequency were monitored using a Capnomac (Datex, Helsinki, Finland). To collect end-tidal gas samples, a small plastic tube was inserted in one of the patient's nostrils, to which topical anaesthetic cream EMLA (Astra, Sweden) had been applied during anaesthesia. At the end of anaesthesia, the nose and pharynx were cleared by suction to ensure free air flow.

Thirty minutes after discontinuation of anaesthesia (10 min after discontinuation of additional oxygen) the patients were given single i.v. doses of morphine 0.1 mg kg^{-1}, pethidine 0.67 mg kg^{-1} or methadone 0.1 mg kg^{-1} as prophylactic analgesic treatment. If the patient was assessed to have pain during the observation period, a rescue analgesic (diclofenac 1 mg kg^{-1} i.v.) was given as indicated. Ventilatory measurements were continued for 2.5 h after administration of the drugs.

Data were collected as a mean value of every 10 s to a central monitoring computer for later analysis. Data were plotted every 2 min for the first 16 min, every 5 min for the next 40 min and then every 10 min for the remainder of the study. All side effects and adverse reactions during the observation period were recorded.

Data were analysed with Systat 5.0, operating system DOS 3.31 run on Compaq Portable 386 [15]. For statistical comparison, all ventilatory and cardiovascular variables were expressed as change from the starting value immediately before administration of the study drugs. Area under the curve (AUC) was calculated for the curves produced by plotting the following variables against time: ventilatory frequency (AUC_{VF}), end-tidal carbon dioxide ($AUC_{E'_{CO_2}}$), end-tidal oxygen ($AUC_{E'_{O_2}}$), peripheral arteriolar oxygen saturation ($AUC_{Sp_{O_2}}$), heart rate (AUC_{HR}), and systolic (AUC_{SAP}) and diastolic (AUC_{DAP}) arterial pressures. All values for AUC were calculated using the linear trapezoidal rule and then normalized to compensate for differences in follow-up time. AUC was used because, as a cumulative index, it provides a better global estimate of a variable than any single value. Acute effects were evaluated by examining the maximum changes of the respective ventilatory and cardiovascular variables. One-way analysis of variance and Student's *t* test for unpaired data were used to compare AUC values between groups. A significant difference was accepted at $P < 0.05$.

RESULTS

Characteristics of the patients in the treatment groups are shown in table I. Predrug values and AUC values with 95% confidence interval (CI) for the ventilatory variables after each drug are shown in table II. Follow-up time was 150 min in all 10 patients in the morphine and methadone groups and seven patients in the pethidine group; three patients in the pethidine group were followed up for 140 min.

After administration of the analgesics, the acute decrease (0–4 min) in ventilatory frequency was significantly greater with pethidine and methadone than with morphine ($P < 0.05$). There was no difference between pethidine and methadone in this respect. AUC_{VF} values were the same in the study groups. Based on the mean ventilatory frequency curves, ventilatory frequency decreased sharply after pethidine and methadone in contrast with morphine, reaching a minimum at 6 and 21 min, respectively (fig. 1).

There was no significant difference in the E'_{CO_2} values between morphine and pethidine. $AUC_{E'_{CO_2}}$ for methadone differed significantly from those of morphine and pethidine ($P < 0.001$). Maximum mean E'_{CO_2} occurred at 12, 6 and 8 min with morphine, pethidine and methadone, respectively. It was significantly ($P < 0.001$) greater with methadone than with morphine or pethidine. Based on the mean E'_{CO_2} curves, E'_{CO_2} values remained increased for 31, 14 and 81 min after morphine, pethidine and methadone, respectively (fig. 1). In individual patients, the greatest E'_{CO_2} values were 6.6–7.6% (mean 7.1 (SD 0.4)%) in the morphine group, 6.7–8.6% (7.5 (0.6)%) in the pethidine group and 7.3–8.4% (8.0 (0.4)%) in the methadone group. The magnitude of increase in E'_{CO_2} individual patients was not related to the predrug E'_{CO_2} or duration of anaesthesia.

$AUC_{E'_{O_2}}$ for methadone was significantly smaller ($P < 0.001$) than that of morphine or pethidine.

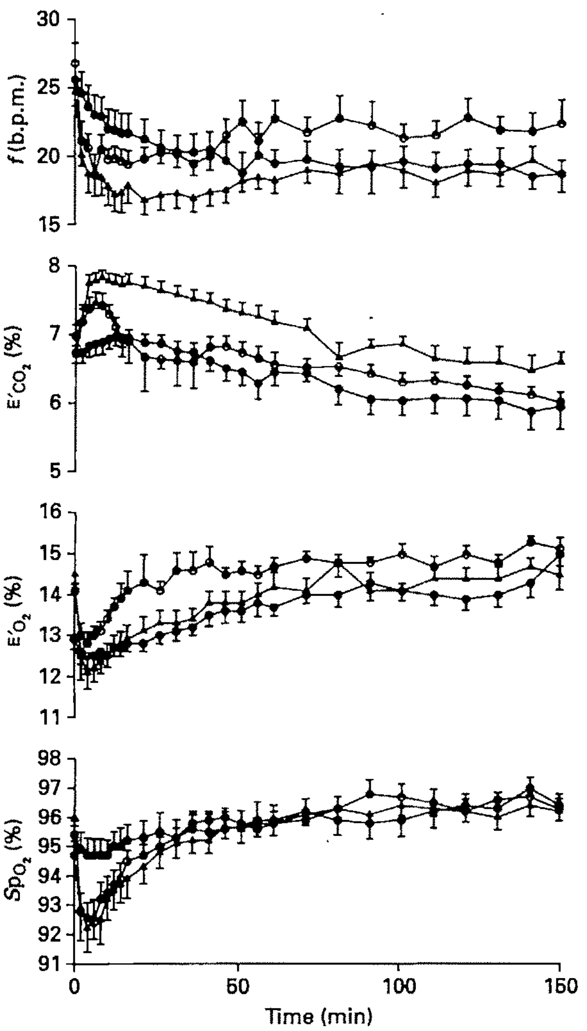

FIG. 1. Mean (SE) ventilatory frequency (*f*), end-tidal carbon dioxide concentrations (E'_{CO_2}), end-tidal oxygen concentrations (E'_{O_2}) and peripheral arteriolar oxygen saturations (Sp_{O_2}) in children after i.v. administration of morphine 0.1 mg kg^{-1} (●), pethidine 0.67 mg kg^{-1} (○) or methadone 0.1 mg kg^{-1} (▲).

Minimum values of the mean E'_{O_2} curves differed significantly ($P < 0.03$) between drugs, being smallest with methadone and greatest with morphine. They occurred at 4 min in all treatment groups. Recovery of the mean E'_{O_2} curves to predrug values occurred at 26, 16 and 61 min with morphine, pethidine and methadone, respectively (fig. 1). The acute decrease in Sp_{O_2} was significantly greater ($P < 0.05$) with methadone than with morphine or pethidine. Sp_{O_2} values differed between morphine and pethidine only at 4 min ($P < 0.036$). $AUC_{Sp_{O_2}}$ values did not differ between the groups. Mean Sp_{O_2} curves recovered to predrug values at 26 min after morphine, 21 min after pethidine and 71 min after methadone (fig. 1).

No child needed additional oxygen or ventilatory support after the administration of the drugs. Criteria for administration of additional oxygen or ventilatory assistance were Sp_{O_2} less than 90 % or ventilatory frequency less than 8 b.p.m. For all three drugs, the time, duration and magnitude of ventilatory changes varied considerably between individuals. Changes in heart rate and arterial pressure were clinically insignificant and did not differ between treatment groups. During the day of operation, nine patients given morphine, nine given pethidine and seven given methadone needed additional analgesic. A second dose of the same opioid was given for severe pain to one patient in the pethidine group (at 2 h 50 min after the first dose), and two patients in the methadone group (at 2 h 45 min and at 1 h 15 min after the first dose). After the administration of the second dose of opioid, ventilatory values of the patient were excluded from the data analysis from the moment of administration. Duration of sleep and analgesia after the drugs and side effects are shown in table III.

TABLE III. *Duration of sleep and analgesia, need of rescue analgesic and side effects on the operation day, after morphine, pethidine and methadone in children. Duration of analgesia = time to administration of rescue analgesic. Mean* (SD) [*range*]

	Morphine ($n = 10$)	Pethidine ($n = 10$)	Methadone ($n = 10$)
Duration of sleep after operation (min)	85 (27) [40–130]	77 (22) [54–110]	107 (32) [25–135]
Patients needing rescue analgesic (No.)	9	9	7
Duration of analgesia after drug (min)	191 (142) [60–525]	171 (166) [63–570]	211 (156) [75–480]
Nausea or vomiting (No. patients)	3	3	3
Urinary retention (No. patients)	1	1	1

DISCUSSION

In this study, anaesthetic and fluid management, positioning of the child and timing of drug administration were standardized in order to permit comparisons. Opioids were not used for premedication or during anaesthesia. Diclofenac was chosen for the primary rescue analgesic because it does not affect ventilation and has been shown to be effective for pain in children [16]. This management is not optimal for prevention of postoperative pain, and the opioid-induced ventilatory depression is superimposed upon recovery from anaesthesia, but this design allows measurements of ventilatory changes in a calm and co-operative child, breathing room air.

The smaller control value of E'_{O_2} in the morphine group compared with those in the two other groups, and the small differences of E'_{CO_2} and E'_{O_2} values from values predicted by the alveolar air equation, may be related to errors in measurements. The relatively high baseline ventilatory frequency and E'_{CO_2} value probably reflect residual halothane effects. However, the mean ventilatory frequency in each group decreased promptly in response to the i.v. opioids. In general, ventilatory frequency proved to be an insensitive indicator of hypoventilation. The greatest E'_{CO_2} value in this study, 8.6 % in a patient in the pethidine group, was associated with a ventilatory frequency of 17 b.p.m. and a temporary decrease in Sp_{O_2} to 87 %. In the methadone group, two patients had maximal E'_{CO_2} values of 8.2–8.3 % with ventilatory frequencies of 14–17 b.p.m. and Sp_{O_2} 91–92%, respectively, but another patient had a maximum E'_{CO_2} value of 8.2% with ventilatory frequency 27 b.p.m. and Sp_{O_2} saturation 90%. Delay between the decreases in E'_{O_2} and Sp_{O_2}, reported in adult patients [14], did not occur in this study, possibly because of the shorter circulation time in young children compared with adults.

The analgesic potencies of morphine, pethidine and methadone have not been compared in children. In the present study it was not possible to assess equianalgesia, but the mean time to rescue analgesia in this study corresponds with the expected duration of analgesia of the three drugs [6]. The doses studied were based on clinical practice of administering i.m. pethidine 1 mg kg^{-1} and morphine 0.15 mg kg^{-1} to children. Morphine and methadone were regarded as equal in potency [6, 10]. It is not known if the ventilatory depressant effects of truly equianalgesic doses of morphine, pethidine and methadone differ in magnitude. However, this study has shown a clear difference in the time course of ventilatory changes.

In adults, pethidine has been shown to produce slight but rarely clinically significant decreases in ventilatory frequency [17–19] or changes in ventilatory volumes or arterial gas tensions with no decrease in ventilatory frequency [20, 21]. In newborn infants, pethidine produces less ventilatory depression than morphine [22]. In older children, ventilatory frequencies were similar after administration of morphine and pethidine [23]. In the present study, acute changes in ventilatory frequency, E'_{CO_2} and Sp_{O_2} after pethidine were steeper, but of shorter duration than after morphine. The shorter effect of pethidine is in agreement with data in adults [6].

In common with previous studies, this study suggests that methadone produces slightly more ventilatory depression than morphine, but the risk of significant hypoventilation is small with the doses used [10–12, 24]. However, larger doses or accumulation of methadone during long-term administration may produce significant ventilatory depression [11, 24, 25]. In our study, methadone produced more prolonged changes in ventilation than morphine or pethidine. This is consistent with the longer duration of analgesia and slower elimination of methadone compared with those of morphine or pethidine [8, 12, 26]. As previously reported in adults [26], the maximal increase in E'_{CO_2} occurred more rapidly after methadone than after morphine. This is consistent with the greater lipid solubility of methadone [27].

ACKNOWLEDGEMENTS

I am grateful to Dr Eeva-Liisa Maunuksela, M.D., PH.D., for guidance during preparation of the study and Dr Klaus Olkkola, M.D., PH.D., for statistical analysis and production of the figures in this paper. I would also like to thank R. N. Riitta Lindelöf. The Paulo Foundation provided a grant.

SUMMARY

We have compared sedation for fibreoptic bronchoscopy provided by incremental doses of midazolam with that provided by a computer-controlled infusion of propofol. These two methods were compared in terms of operator and patient acceptability, anxiolysis, effects on systolic arterial pressure and oxygen saturation. Tests were made also of memory and motor reactions, before and 60 min after the end of the procedure. Acceptability to operators and patients was high in both groups. There were no significant differences between the groups in systemic arterial pressure or anxiolysis. Oxygen saturation decreased in both groups (propofol group median 83% (range 69–95%); midazolam group median 86% (range 77–95%)) (ns). The median recovery time was 5 min (range 5–10 min) in the propofol group and 10 min (range 5–40 min) in the midazolam group ($P < 0.01$*). Memory and motor reaction times 60 min after the end of the procedure did not differ from baseline in the propofol group, but were significantly impaired in the midazolam group.* (Br. J. Anaesth. 1993; **70**: 419–422)

KEY WORDS

Anaesthetic techniques: bronchoscopy, i.v. sedation. Anaesthetics, intravenous: propofol. Hypnotics, benzodiazepines: midazolam.

Flexible fibreoptic bronchoscopy is a technique used commonly by respiratory physicians in the management of patients with many types of respiratory disease. However, it is associated with both morbidity and mortality. Most deaths and complications associated with bronchoscopy arise from the procedure itself, but at least five deaths and up to 50% of the major life-threatening complications have been related to the sedative regimen used [1].

Systemic arterial desaturation occurs during bronchoscopy, and may be caused by several factors, including topical anaesthesia [2, 3], sedation [4], partial airway obstruction [2], abnormal distribution of ventilation [2] and reflex response to bronchoscopy and lavage [5]. If the desaturation persists after the end of the procedure, this is most likely to result from oversedation, as the other factors produce only transient changes.

Persistence of sedation beyond the end of the procedure is undesirable in the outpatient, as this may result in detention of the patient in hospital. Although bronchoscopy may be performed without sedation, one study has reported that 60% of the patients who did not receive sedation found this very unpleasant or intolerable [6].

The ideal agent for sedation in bronchoscopy should provide amnesia, anxiolysis and analgesia, such that the patient is comfortable, co-operative with the bronchoscopist and willing, if necessary, to return for a repeat procedure [1].

We have attempted to ascertain how well these conditions are achieved with a low-dose infusion of propofol. We have compared the sedation and recovery associated with propofol with that associated with midazolam, which is commonly used to provide sedation for bronchoscopy.

PATIENTS AND METHODS

After obtaining Ethics Committee approval, we studied 42 patients undergoing fibreoptic bronchoscopy, with their written informed consent. They were allocated randomly to receive either propofol or midazolam. Patients and bronchoscopists were blinded to the type of sedation used. Patients were excluded if they were currently receiving, or had recently taken, a benzodiazepine.

Patients' weight was recorded, with baseline measurements of heart rate, arterial pressure and oxygen saturation. Memory was tested using E. K. Warrington Memory Recognition Tests. These are psychological tests used to assess short-term recall of 25 words and faces, generating a score (maximum 25) for each. Motor performance was assessed using a Motor Reaction Timer. This is a device whereby the patient switches off a series of coloured lights which are activated by the assessor, and the machine resolves the movement into a decision time and a movement time, both in seconds. Each patient completed a 10-cm visual analogue scale (VAS) for

anxiety, and was assessed in performance of a finger–nose test.

Each patient received 4% nebulized lignocaine 4 ml, followed by topical lignocaine 10 mg to each nostril and to the oropharynx. Further 2-ml increments of 4% lignocaine were administered via the bronchoscope by the operator as required. Three bronchoscopists (two consultants and one senior registrar) performed all of the procedures. All bronchoscopies were performed with the patient in a semi-recumbent position.

Propofol and midazolam were administered via a 20-gauge cannula sited in the dorsum of the hand. Propofol was infused, and the rate of infusion controlled by the Psion Organiser–Ohmeda 9000 Infusion Pump system devised by Kenny and White [7]. An initial target blood concentration was selected of 1.5 $\mu g\ ml^{-1}$ for a period of 2 min, and this was increased incrementally each 1 min by 0.25 $\mu g\ ml^{-1}$ until 2.0 $\mu g\ ml^{-1}$, and thereafter in 0.1-$\mu g\ ml^{-1}$ increments each 1 min until adequate sedation was achieved. Those patients receiving midazolam were given initially a 2-mg bolus, and after 2 min were given increments of 1 mg min^{-1} until adequate sedation was achieved. Patients and operators were blinded to the drug administered, as follows: each patient was connected to a propofol infusion via a 200-cm manometer line with a three-way tap at the i.v. cannula. These were then covered with a large surgical sheet. The infusion device was activated in all patients, but was not programmed to deliver in the patients receiving midazolam; in these patients, the midazolam was given at the level of the three-way tap. Patients receiving propofol were given sterile water at intervals to blind the sedation further. The sedation score described by MacKenzie and Grant [8] was used and the patients were judged to be sedated adequately by the bronchoscopist when they had closed eyes but were rousable to command.

An anaesthetist was present throughout each procedure, and was responsible for administration of the sedation, and for monitoring of the patient. Each patient was monitored by sphygmomanometer and by Ohmeda Biox 3700 pulse oximeter. Arterial pressure was recorded at intervals of 2 min, and pulse oximetry data were recorded using an interface to a Psion Organiser POS 200 hand-held computer. Oxygen was administered by nasal catheter if oxygen saturation decreased to less than 85%. Pulse oximetry was continued until 60 min after the end of the procedure, and the data recorded were subsequently retrieved and analysed manually.

Recovery was judged to have occurred when there was return of spontaneous eye opening, correct recall of date of birth and ability to perform the finger–nose test without past pointing. These tests were repeated at 5, 10, 15, 20, 30, 40 and 60 min after the end of the procedure, until recovery occurred. The Memory Recognition Tests, Motor Reaction Tests and Visual Analogue Scale for anxiety were repeated 60 min after the end of the procedure, at which point study of the patients finished.

Patients completed a questionnaire 60 min after the procedure. The bronchoscopists also completed a questionnaire. All patients were given a set of written postoperative instructions and were accompanied home by a relative or friend.

TABLE I. *Patient characteristics (mean (range or SD)).* *P < *0.05* *(Student's* t *test for the means of two groups)*

	Midazolam		Propofol
Age (yr)	63.5 (48–85)		63.9 (38–81)
Weight (kg)	54.85 (10.44)	*	63.65 (10.63)
Systolic AP (mm Hg)	140 (31.1)		135 (23.3)
Heart rate (beat min^{-1})	85.8 (13.4)		84.5 (13.1)
Sp_{O_2} (%)	95.2 (2.3)		95 (2.1)

TABLE II. *Time to sedation and total duration of procedure (mean (SD))*

	Midazolam	Propofol
Time to sedation (min)	4.2 (2.6)	4.7 (2.1)
Duration of procedure (min)	17.4 (4.3)	20.8 (10.4)

Data were analysed by chi-square test, Student's *t* test for the means of two samples, and Wilcoxon's Rank Sum Test as appropriate. $P < 0.05$ was accepted as statistically significant.

RESULTS

At the conclusion of the study, there were 21 patients in each group, but it became apparent that there were more males in the propofol group ($n = 16$) than in the midazolam group ($n = 9$) ($P < 0.05$, χ^2 test with Yates' correction). This was reflected in the greater mean weight in the propofol group (63.65 (SD 10.63) kg), than in the midazolam group (54.85 (10.44) kg) ($P < 0.02$, Student's *t* test for the means of two groups).

Otherwise, the two groups were similar in age and baseline recordings of arterial pressure, heart rate and oxygen saturation (table I). There were four patients of ASA grade II and 17 of ASA grade III in the midazolam group, and five of ASA grade II with 16 of ASA grade III in the propofol group.

The time to sedation and total duration of procedure were similar in the two groups (table II).

The median dose of midazolam was 6 mg (0.0063 mg kg^{-1} min^{-1}) (range 3–18 mg). The patient who received 18 mg had a particularly high alcohol intake; the next greatest dose was 10 mg. The median dose of propofol was 155 mg (0.1171 mg kg^{-1} min^{-1}); this equates with an average anaesthetic induction dose. The range of doses was 71–420 mg; the patient who received 420 mg underwent a procedure which lasted 60 min; and the next greatest dose was 350 mg.

Extra sedation was requested by the bronchoscopist for seven patients in the midazolam group and four patients in the propofol group. Three patients in the midazolam group became unresponsive to command during the procedure, as did five patients in the propofol group; in the latter patients, there was rapid return of an appropriate level of sedation on reduction of the rate of infusion of propofol. However, in the patients in the midazolam group, the oversedation persisted until the end of the procedure.

There were no differences between the two groups

in mean greatest or mean least systolic arterial pressure measured during the procedure.

Oxygen saturation decreased during the procedure in every patient in both groups. Median least oxygen saturation in the propofol group was 83% (range 69–95%); that in the midazolam group was 86% (range 77–95%) (ns). There were no statistically significant differences in mean oxygen saturation between the two groups at the time recovery was said to have occurred, or at 60 min after the end of the procedure. Additionally, in both groups at each of these times, mean oxygen saturation was not significantly different from baseline. Seven patients in each group required administration of oxygen during the procedure. Four patients in each group suffered desaturation after sedation, but before introduction of the bronchoscope, and in each this was by 10 or more percentage points from the baseline saturation. Each of these patients had baseline saturations of > 95% breathing air, and the desaturation continued after insertion of the bronchoscope.

Median time to recovery was twice as long in the midazolam group (10 min, range 5–40 min) as that in the propofol group (median 5 min, range 5–10 min) ($P < 0.01$, Wilcoxon rank sum test). Twenty of the propofol patients had recovered by 5 min and only one patient required 10 min (fig. 1).

There were no statistically significant differences between the two groups in preoperative assessment of memory or of motor reaction times. Similarly, there were no differences between baseline measurements in the propofol group and those taken 60 min after the end of the bronchoscopy. However, in the midazolam group these tests produced results at 60 min which were significantly worse than baseline (table III).

Postoperative VAS anxiety scores were comparable in each group, and were substantially smaller than those recorded before sedation began.

The results of a questionnaire completed by the bronchoscopists after the end of the procedure revealed similar levels of satisfaction for both sedative regimens. The results of the patient questionnaire showed similar levels of satisfaction in each group, 100% of patients finding the procedure to be comfortable. Two patients in the propofol group and one patient in the midazolam group recalled insertion of the bronchoscope, but none of these patients was distressed.

No patient who received propofol complained of pain as a result of infusion of this drug, although this information was not specifically sought.

DISCUSSION

The blood concentrations of propofol predicted by this delivery system have been validated during its use in general anaesthesia [7, 9]. Despite the apparent complexity of this system, we have shown that the time taken to achieve adequate sedation was comparable to the time taken using incremental doses of midazolam (the recommended method of administration of midazolam [10]). Using an incremental technique, the median dose of midazolam was approximately twice the dose advised by Roche in the product Data Sheet for a patient of the mean weight in the midazolam group [10]. Using incremental intervals of 1 min, three patients in the midazolam group became unresponsive to command. Incremental intervals of 2 min may therefore be more appropriate for this drug in order to reduce the incidence of oversedation; this measure might reduce the acceptability of midazolam in procedures lasting an average of 20 min.

It is well known that propofol may cause hypotension, when given as a bolus or by infusion to produce anaesthesia. However, it has been shown to be devoid of cardiorespiratory side effects when used in small doses to provide sedation [8]. Sedation with midazolam may cause hypotension [11]; both drugs had no adverse effects on arterial pressure in the current study.

Both propofol and midazolam may produce respiratory depression [4]. In this study, equal numbers of patients in each group suffered severe arterial desaturation as a result of sedation alone, before the effect of the bronchoscope and washing solutions. Median least oxygen saturation recorded during the procedure was smaller in the propofol group than in the midazolam group, although this was not statistically significant. However, it has been shown that, when midazolam is used in combination with fentanyl (as may be more usually the case in sedation for bronchoscopy), these two agents act synergistically rather than additively [12]. Potential for greater desaturation than that shown in this study would seem to be present with this commonly used combination of agents.

The results of our tests of memory and motor reactions show clearly that, when midazolam is used for sedation in this procedure, there remains significant impairment of memory and motor reactions 60 min after the end of the procedure. A recent study using a battery of tests of recovery has shown that central nervous system impairment may persist for at least 3.5 h after flumazenil antagonism of midazolam sedation, although patients may have a subjective feeling of alertness which may have dangerous consequences [13]. This is certainly undesirable in outpatients, and highlights the unsuitability of this "short-acting" benzodiazepine for sedation in procedures of short duration. The results of the memory and motor reaction tests for patients in the propofol group were different from those of the midazolam group; at 60 min, they were not significantly different from the baseline, pre-sedation results. With particular reference to the motor reaction tests, it can be seen that both mean decision time and mean movement time were shorter at 60 min after the end of the procedure, although this was not statistically significant. It would appear that these patients had recovered sufficiently to be able to recall their pre-sedation experience of the motor reaction timer and to improve on their performance with it.

We have demonstrated that, if used cautiously and if dosage is titrated to effect, it is possible to use midazolam alone for sedation in fibreoptic bronchoscopy, without detriment to oxygen saturation after the end of the procedure. However, its effects on memory and motor performance make it, in our opinion, less suitable for use in the outpatient.

In a major review of sedation for fibreoptic bronchoscopy [1], the authors stated: "no single agent provides amnesia, anxiolysis and analgesia, so a combination of drugs is necessary." We consider that an infusion of propofol, after topical lignocaine anaesthesia, provides conditions which come close to this ideal. In addition, the rapid onset and short duration of action of propofol allow rapid changes in depth of sedation and swift recovery without the need for expensive antagonist agents. These are particularly important features because, even with the cautious administration used in both groups of this study, it is possible to exceed the limits of sedation and approach anaesthesia. This possibility leads us to recommend that the administration of sedation for endoscopic procedures should be the responsibility of a medical practitioner experienced in both management of the airway and the use of the drugs given.

The evanescent nature of the effects of propofol may make this the most appropriate drug for use in the "high-risk" patient, in whom ease of change of depth of sedation, rapid recovery and cardiovascular stability are essential requirements. Hypoxaemia undoubtedly still occurs during bronchoscopy with this agent, but sedation is not the only cause, and it may be prevented easily by administration of oxygen via a nasal catheter.

COMPARISON OF INFUSION RATES OF THREE I.V. ANAESTHETIC AGENTS FOR INDUCTION IN ELDERLY PATIENTS

M. C. BERTHOUD, G. A. McLAUGHLAN, I. J. BROOME, P. D. HENDERSON, J. E. PEACOCK AND C. S. REILLY

SUMMARY

We have compared the effect of different rates of injection of 2.5% thiopentone, 0.5% methohexitone and 0.2% etomidate for induction of anaesthesia in 90 premedicated, elderly patients. The agents were administered by infusion pump at rates of 1200 ml h^{-1}, 600 ml h^{-1} and 300 ml h^{-1}, respectively until anaesthesia was induced as judged by loss of verbal contact with the patient. The times for induction were significantly greater with the slower infusion rates (thiopentone 41 s, 57 s and 91 s ($P < 0.001$); methohexitone 44 s, 62 s and 84 s ($P < 0.01$); etomidate 48 s, 59 s and 87 s ($P < 0.001$)). The doses were significantly smaller ($P < 0.001$) with the slower infusion rates for all three agents (thiopentone 5.0, 3.7 and 2.8 mg kg^{-1}; methohexitone 1.00, 0.75 and 0.56 mg kg^{-1}; etomidate 0.26, 0.15 and 0.11 mg kg^{-1}). For each drug there was no significant difference in induction characteristics, oxygen saturation, heart rate or mean arterial pressure, at the different infusion rates. (Br. J. Anaesth. 1993; **70**: 423–427)

KEY WORDS

Age factors: elderly. Anaesthetic techniques: i.v. infusion. Anaesthetics, intravenous: etomidate, methohexitone, thiopentone.

In a previous study, we have shown that a slower rate of administration of propofol for induction of anaesthesia in elderly patients resulted in smaller dose requirements [1]. Using an Ohmeda 9000 syringe pump to control accurately the rate of administration of propofol at 5, 10 and 20 ml min^{-1}, we demonstrated that the dose requirements for induction could be reduced markedly, and that this was accompanied by a significant reduction in the incidence of apnoea, and the degree of hypotension. In the present study, we have examined the effect of infusion rate on the induction dose requirement and plasma concentrations of thiopentone, methohexitone and etomidate. We have also examined the effect of infusion rate on induction characteristics, such as the incidence of pain on injection or apnoea, and on arterial pressure, oxygen saturation and heart rate.

PATIENTS AND METHODS

We studied 90 patients of class ASA I or II, aged 60 yr or older, undergoing elective body surface or urological surgery and who did not require tracheal intubation as part of the planned anaesthetic technique. Patients were excluded if they had clinical evidence of respiratory, cardiac, hepatic, renal or endocrine disease, uncontrolled hypertension, previous adverse response to general anaesthesia, body weight more than 20% greater than ideal, or were receiving any medication likely to influence the course of anaesthesia or haemodynamic response.

The study was approved by the local Ethics Committee, and written informed consent was obtained from all patients. One investigator collected data for each agent: thiopentone (M.B.), methohexitone (G.McL.) and etomidate (I.B.). Temazepam 20 mg was given orally 1 h before induction of anaesthesia. In the anaesthetic room an i.v. cannula was inserted into each arm, one for the administration of drugs and the other for venous sampling. Patient monitoring consisted of non-invasive arterial pressure (Dinamap), ECG and pulse oximetry.

All patients were asked to report any discomfort on i.v. injection of the anaesthetic drug and were asked also to keep talking as long as they could in response to open-ended questioning after the start of injection. They were then given fentanyl 0.75 μg kg^{-1} i.v., 5 min before the induction of anaesthesia. Patients were allocated randomly to one of three groups to receive the selected drug by infusion at rates of 1200, 600 or 300 ml h^{-1} (equivalent to 5, 10, or 20 ml min^{-1}) for induction of anaesthesia, using an Ohmeda 9000 syringe pump. The induction agents were used in concentrations calculated to administer approximately equipotent doses over a 30-s period at the 1200-ml h^{-1} infusion rate. The concentrations of drugs used were thiopentone 25 mg ml^{-1}, etomidate 2 mg ml^{-1} and methohexitone

5 mg ml^{-1}, which would result in doses of 3.6 mg kg^{-1}, 0.28 mg kg^{-1} and 0.70 mg kg^{-1} respectively, for a 70-kg individual over a 30-s infusion period. Anaesthesia was defined as loss of verbal contact with the patient, at which point the infusion was discontinued. For maintenance of anaesthesia, the patients breathed a mixture of 66 % nitrous oxide in oxygen, with enflurane according to clinical requirements, via a mask and a Mapleson D system.

The rate of infusion, the duration of induction and the total induction dose were recorded. Cardiovascular measurements were made before and 4 min after fentanyl, at the end of induction, and at 2-min intervals for 10 min after induction. Peripheral oxygen saturation was recorded at the same times using a pulse oximeter. Periods of apnoea greater than 30 s were treated by intermittent positive pressure ventilation and periods of oxygen desaturation to 90 % or less were treated with increased inspired oxygen concentrations. The incidence of any period of apnoea greater than 30 s, any pain on injection and the presence of excitatory or other side effects were noted.

Blood samples were obtained at 2, 5 and 10 min after induction. The serum was extracted and frozen to −20 °C within 30 min for subsequent analysis. Drug analysis was performed using HPLC with u.v. detection. The internal standards were flunitrazepam for thiopentone [2, 3], hexobarbitone for methohexitone [4] and propoxate for etomidate [5]. The coefficients of variation for analysis of thiopentone were 2.84 % at 1 μg and 3.7 % at 10 μg, of methohexitone were 2.98 % at 1 μg and 3.26 % at 10 μg, and of etomidate were 3.05 % at 120 ng and 0.85 % at 460 ng. The lower limit of detection for thiopentone was 1.0 μg, for methohexitone was 0.2 μg and for etomidate was 25 ng.

Statistical analysis was performed using Analysis of Variance with Tukey's HSD test to compare patient data, induction times, induction doses and serum concentrations of drugs. Repeat Measures Analysis of Variance was used for arterial pressure, heart rate and oxygen saturation. Chi-square analysis was used to compare the incidence of apnoea and pain on injection.

RESULTS

The patients receiving thiopentone 600 ml h^{-1} for induction were significantly older than those receiving 300 ml h^{-1}. The patients receiving methohexitone 1200 ml h^{-1} were significantly younger than those receiving 300 ml h^{-1}. There were no other significant differences between infusion rate groups (table I).

All patients were anaesthetized successfully using the regimen described. The patients receiving the induction agents at 1200 ml h^{-1} had mean induction times of 40–48 s; the time was 84–90 s in those receiving the induction agent at 300 ml h^{-1} (table II). The differences in induction time between the different infusion rate groups was significant for all agents ($P < 0.001$ for thiopentone and etomidate; $P < 0.01$ for methohexitone). Those patients receiving 1200 ml h^{-1} had mean induction doses of 5.0 mg kg^{-1} for thiopentone, 1.0 mg kg^{-1} for methohexitone and 0.26 mg kg^{-1} for etomidate, decreasing to 2.8 mg kg^{-1}, 0.56 mg kg^{-1} and 0.11 mg kg^{-1}, respectively, in patients receiving 300 ml h^{-1}. These differences between induction rate groups were significant for all three agents ($P < 0.001$).

For all three induction agents, the serum concentration decreased with time and with decreasing infusion rate (fig. 1). The difference in thiopentone concentration was significant at 5 min ($P = 0.002$) and 10 min ($P = 0.003$); that in methohexitone concentration was significant at 10 min ($P = 0.016$).

The area under the concentration–time curve (AUC) from 2 min to 10 min was calculated using the trapezoidal rule for each patient (table II). Those patients receiving the faster infusions had larger AUC. These differences were significant in patients receiving thiopentone ($P = 0.016$) and methohexitone ($P = 0.025$), but not in those receiving etomidate. The correlation coefficients of dose against AUC were calculated for each patient: $r = 0.671$ for thiopentone, $r = 0.682$ for methohexitone and $r = 0.607$ for etomidate (significant at $P < 0.001$).

No patient receiving thiopentone or methohexitone experienced pain on injection. Of the

patients receiving etomidate, two in the 300-ml h^{-1} group, seven in the 600-ml h^{-1} and five in the 1200-ml h^{-1} group experienced pain on injection. One patient receiving each of the faster rates of infusion complained that the pain was severe (table III).

There was no statistical difference between induction rate groups, for each infusion rate, with respect to the incidence of apnoeic episodes more than 30 s in duration and the mean duration of apnoea (table III).

From baseline mean of 96.2 %, oxygen saturation decreased after induction in the patients receiving methohexitone and thiopentone. For the infusion rates of 300 ml h^{-1}, 600 ml h^{-1} and 1200 ml h^{-1}, the percentage decreases in saturation in the patients receiving thiopentone were 3.1 %, 5.7 % and 6.9 % and in those receiving methohexitone were 6.5 %, 8.3 % and 2.9 %, respectively. At 2 min all these patients had oxygen saturations which had recovered to baseline values or greater, and these were maintained throughout the study. The etomidate group did not show this pattern and patients maintained their oxygen saturation after induction and later. There was no significant difference in oxygen saturation between infusion rates. The power of this finding was 0.75 using a postulated difference of oxygen saturation of 3 %.

Patients receiving thiopentone 1200 ml h^{-1} and 600 ml h^{-1} had an increase in heart rate from a baseline of 74 (SD 12.76) beat min^{-1} to 81 (14.28) beat min^{-1} and 76 (12.29) beat min^{-1}, respectively, immediately after induction. All the patients receiving methohexitone had increases in heart rate at the end of induction. From a baseline of 71 (8.1) beat min^{-1} the heart rate increased to 78.2 (8.2) beat min^{-1} in patients receiving 300 ml h^{-1}, 79.8 (9.0) beat min^{-1} in those receiving 600 ml h^{-1} and 74.2 (16.3) beat min^{-1} in those receiving 1200 ml h^{-1}. This was followed by a steady decline in heart rate of between 11% and 25% in the patients receiving thiopentone and of 2.7% and 6.2% in the patients receiving methohexitone. All patients receiving etomidate had only a steady decrease in heart rate of between 12.1% and 21.1% throughout the study period. None of these changes reached statistical significance between infusion rate groups. The power of this finding was 0.68 using a postulated difference in heart rate of 20%.

All patients had a steady decline in mean arterial pressure throughout the study. In the 300-ml h^{-1} group, the mean arterial pressure decreased by 30.1% in patients receiving thiopentone, 5% in those receiving methohexitone and 27.5% in those receiving etomidate. For the 600-ml h^{-1} group these values were 39.4%, 2.7% and 28.3%, respectively, and for the 1200-ml h^{-1} group, 23.2%, 6.2% and 28.3% (no statistical significance between induction rate groups). The power of this finding was 0.8 using a postulated difference in mean arterial pressure of 20%.

DISCUSSION

We have demonstrated that by reducing the rate of administration of thiopentone, methohexitone and etomidate, the induction dose given can be reduced to about 50% of the recommended dose. This is achieved at the expense of a longer induction time. These findings are similar to those described for propofol [1, 6].

In addition, we have measured plasma concentrations of these agents and found them to be reduced in the patients receiving slower infusion rates. The differences in serum concentrations of drug at 2 min were not significant because of a wide variation, probably as a result of incomplete mixing so soon after the start of induction. More complete mixing had occurred by 5 and 10 min, reducing the variation in drug concentration within infusion rate groups. Thus significance was reached at both 5 and 10 min after induction for thiopentone, and at 10 min for methohexitone. Although statistical significance was not reached in the etomidate group, the results demonstrate a trend similar to observations after administration of barbiturates. The AUC values calculated using these results confirm the above findings.

When a drug is administered until its action is observed to have taken effect, the amount required to induce anaesthesia depends on several factors: the free concentration of the drug in the plasma; the time it takes that drug to reach its target organ; the time it takes the drug to enter into the target organ in sufficient concentration; and the time it takes to exert its pharmacological action.

In patients given an i.v. agent at a fast infusion rate, a large amount of drug is given before it is able to reach the target organ. Thus the most important factor determining the dose given is the amount of drug that can be given in the time it takes for the drug to reach the target organ (or the "arm–brain circulation time"). The delay in the drug entering the central nervous system and exerting its action (biophase delay) is short, as the concentration gradient between blood and brain is large because of the larger dose. Attempting to titrate a dose against response in patients in whom anaesthesia is induced by fast infusion leads to overshoot, and so to overdose. This explains the findings with the 1200-ml h^{-1} infusion rate—a rate which corresponds, with thiopentone, to giving 250 mg over 30 s.

In patients given an i.v. anaesthetic agent by a slow infusion, the concentration of the drug in blood, and therefore in the brain, takes time to build up to a value sufficient to act. This may last as long as several complete circulations. This delay, together with the slower rate of administration, has the effect that overshoot is reduced, the total dose given being closer to the minimum dose required to achieve induction.

It is likely that reduction of delivery of a drug to less than a particular rate results in redistribution and elimination of the agent becoming significant factors in determining the rate at which sufficient plasma concentrations are reached, and the overall dose required to achieve induction may even begin to increase.

In a study by McCollum and Dundee comparing the induction characteristics of four i.v. anaesthetic agents [7], none of the patients receiving etomidate was apnoeic, but 30% of the patients receiving thiopentone and 20% of patients receiving methohexitone were so. In our study, the incidence of apnoea and respiratory depression were less in those patients receiving etomidate than in those receiving a barbiturate. These differences between agents are reflected in the pattern of change in oxygen saturation on induction.

Thiopentone and methohexitone also appeared to behave differently from etomidate in their effects on the cardiovascular system. The barbiturates produced an initial increase in heart rate after induction, followed by a decrease with deepening anaesthesia, the heart rate decreasing steadily throughout with etomidate. This early increase in heart rate with thiopentone has already been described [8]. In our study, the mean arterial pressure decreased with all three agents, probably because of cardiovascular depression caused by the maintenance of anaesthesia with enflurane. Enflurane was used to maintain anaesthesia in order to allow continuing sampling of plasma concentrations of the induction agent. The fact that we have been unable to demonstrate a significant difference in heart rate or mean arterial pressure between induction rate groups is at variance with the study using propofol. This difference may be accounted for in part by propofol causing more haemodynamic changes than the other agents [9, 10].

The recommended dose of an induction agent is that dose required to produce its effect in one arm–brain circulation time; this represents a dose greater than that needed to achieve sleep. Inducing anaesthesia in patients gradually may not eliminate the incidence of apnoea and hypotension, but perhaps we should re-assess the concept that an i.v. induction agent should be effective in a time approaching that taken by the blood to circulate from the arm to the brain.

HAEMODYNAMIC CHANGES PRODUCED BY INHALATION ANAESTHETICS IN THE PRESENCE OF PHOSPHODIESTERASE INHIBITION

G. MOLTER, R. LARSEN, U. PETERS, U. BAUCH AND R. SEFRIN

SUMMARY

We have investigated the circulatory effects of halothane and isoflurane in the presence of the phosphodiesterase inhibitor, enoximone, in 20 patients, ASA class III, aged 40–70 yr, undergoing coronary artery bypass grafting. After induction of anaesthesia (midazolam, fentanyl, etomidate and pancuronium) all patients received enoximone 0.5 mg kg^{-1}, followed, 10 min later, by either halothane 1 MAC (group I; n = 10) or isoflurane 1 MAC (group II; n = 10). Haemodynamic variables were measured and blood samples (arterial and mixed venous) were obtained before (control, t_0), 5 (t_1) and 10 (t_2) min after the injection of enoximone and immediately (t_3) and 5 (t_4) min after steady state conditions with halothane or isoflurane, as verified by the end-expiratory concentration. Heart rate, mean arterial pressure (MAP), mean pulmonary artery pressure, pulmonary capillary wedge pressure and right atrial pressure were recorded. Cardiac (CI) and stroke volume indices, systemic (SVR) and pulmonary vascular resistance, oxygen availability ($\dot{Q}O_2$), oxygen consumption and oxygen extraction rate were calculated using standard formulae. MAP decreased significantly in both groups after bolus injection of enoximone (group I: 11%; group II: 7%). Under steady state conditions with the volatile anaesthetics, a further significant decrease in MAP was observed (group I: 12%; group II: 12%). Enoximone produced a significant increase in CI (group I: 25%; group II: 27% compared with control). After administration of isoflurane, CI remained essentially unchanged, while halothane decreased CI significantly by 20%. In both groups, SVR decreased significantly after administration of enoximone (group I: 26%; group II: 24%). After isoflurane, there was a further significant decrease in SVR of 10%, whereas there was no change with halothane. After bolus injection of enoximone, $\dot{Q}O_2$ increased significantly (group I: 30%; group II: 23%). After halothane, $\dot{Q}O_2$ decreased significantly (20%), while with isoflurane there was no change. Oxygen extraction decreased significantly with enoximone (group I: 10%; group II: 15%); with halothane, it returned to control values, but it remained almost unchanged with isoflurane. (Br. J. Anaesth. 1993; **70**: 428–433)

KEY WORDS

Anaesthetics volatile: halothane, isoflurane. Pharmacology: enoximone.

In isolated heart muscle, equianaesthetic concentrations of halothane and isoflurane have similar negative inotropic effects. However, with enhanced active tension mediated by potentiating patterns of electrical stimulation, isoflurane has less negative inotropic action than halothane [1, 2]. It might be of greater clinical relevance if volatile anaesthetics have comparable depressant effects on a myocardium exposed to the positive inotropic action of cardiotonic agents. In order to examine this question, we have investigated the haemodynamic responses to halothane and isoflurane in the presence of enoximone.

PATIENTS AND METHODS

The study was approved by the local Human Subjects Medical Ethics Committee and patients' informed written consent was obtained. We studied 20 patients, ASA class III, aged 40–70 yr, undergoing coronary artery bypass grafting. All patients were receiving nitrates (isosorbide dinitrate) and calcium channel blockers (nifedipine) before operation. Patients with congestive heart failure (NYHA classification II–IV), an ejection fraction of less than 45%, renal failure (serum creatinine > 100 µmol litre^{-1}), medication with digitalis glycosides or beta-adrenergic receptor antagonists, or thrombocytopenia of platelets < 80000 µl^{-1} were excluded from the studies. The patients were allocated randomly to two groups (10 in each) according to a computerized allocating schedule.

Patients were premedicated with flunitrazepam 2 mg orally 1 h before arrival in the operating theatre. At the same time, the patient's scheduled oral medication with nitrates and calcium channel blockers was administered. Cutaneous electrodes were positioned for continuous electrocardiographic recording of leads II and V and continuous ST segment analysis (Sirecust 906, Siemens Inc.,

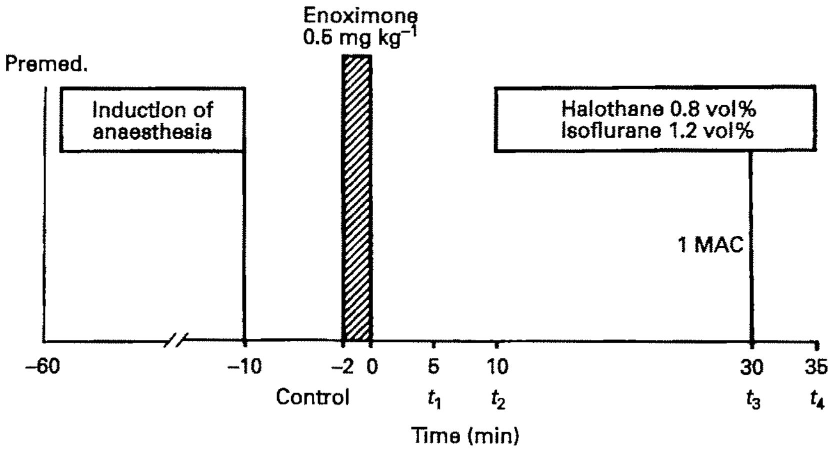

FIG. 1. Study design. After induction of anaesthesia every patient received enoximone 0.5 mg kg^{-1} i.v. within 2 min. Ten minutes after termination of that injection, patients received 1 MAC of either halothane (group I, $n = 10$) or isoflurane (group II, $n = 10$). Haemodynamic measurements were performed and blood samples were drawn before the injection of enoximone (control (t_0)) and 5 (t_1) and 10 (t_2) min after the bolus application of enoximone and immediately (t_3) and 5 (t_4) min after steady-state conditions with the volatile anaesthetics had established.

Danvers, MA, U.S.A.). Myocardial ischaemia was defined as a decrease in the ST level of more than 0.2 mV. After insertion of a venous cannula into a forearm vein and a 20-gauge Teflon cannula into the radial artery of the non-dominant arm, anaesthesia was induced with midazolam 1–2 mg, fentanyl 7–10 µg kg^{-1}, etomidate 0.2–0.3 mg kg^{-1} and pancuronium 0.1 mg kg^{-1}. The lungs were ventilated to normocapnia ($F\text{I}_{\text{O}_2}$ 1.0) (Sulla 808 V, Drägerwerk AG, Lübeck, FRG). A balloon-tipped thermodilution catheter was positioned in the pulmonary artery via the right internal jugular vein (7.5-French gauge pulmonary artery catheter, Baxter Lab., FRG). Catheter placement was determined by pressure tracing and confirmed by radioscopy. The catheters were connected to pressure transducers (Medex, Haslington, England) interfaced with a multichannel monitor and recorder (sirecust 906, siredoc 220, Siemens Inc. Danvers, MA, U.S.A.) for continuous monitoring of systemic arterial, pulmonary arterial and central venous pressure. Throughout the investigation period, crystalloid solution 10–15 ml kg^{-1} was administered.

Study design (fig. 1)

Ten minutes after induction of anaesthesia, each patient received enoximone 0.5 mg kg^{-1} within 2 min. Ten minutes later, 1 MAC (end-expiratory in oxygen) of either halothane (group I) or isoflurane (group II) was administered. Haemodynamic and oxygenation values (blood–gas analysis) (Stat profile 5, Nova biomedical, Waltham, MA, U.S.A.) were measured before injection of enoximone (control, t_0) and 5 (t_1) and 10 (t_2) min after the bolus administration of enoximone and immediately (t_3) and 5 (t_4) min after steady-state conditions with the volatile anaesthetics were established, as verified by the end-expiratory concentrations of halothane and isoflurane (Capnomac, Hoyer AG, Bremen, FRG).

Measured variables

The following haemodynamic variables were recorded: heart rate (HR), mean arterial pressure (MAP), right atrial pressure (RAP), mean pulmonary artery pressure (MPAP), pulmonary capillary wedge pressure (PCWP), cardiac output (CO).

Calculated variables

Systemic vascular resistance (SVR), pulmonary vascular resistance (PVR), cardiac index (CI), stroke volume index (SVI), oxygen availability ($\dot{Q}\text{O}_2$), oxygen consumption ($\dot{V}\text{O}_2$) and oxygen extraction rate ($\dot{V}\text{O}_2/\dot{Q}\text{O}_2$) were calculated by means of commonly used formulae:

SVR = (mean arterial pressure (MAP) —right atrial pressure (RAP)) × 80/cardiac output (CO)
PVR = (mean pulmonary artery pressure (MPAP) —left atrial pressure (LAP)) × 80/cardiac output (CO)
CI = cardiac output (CO)/body surface area (BSA)
SVI = stroke volume (SV)/body surface area (BSA)
$\dot{Q}\text{O}_2$ = cardiac output (CO) × arterial oxygen content ($C\text{a}_{\text{O}_2}$)
$\dot{V}\text{O}_2$ = cardiac output (CO) × arterio–mixed venous oxygen difference ($P\text{a}_{\text{O}_2}$–$P\bar{\text{v}}_{\text{O}_2}$)

Statistics

Mean values were calculated and within-group statistical analysis was performed using Friedman's test followed by a Wilcoxon–Wilcox test. In order to evaluate difference between groups, a Mann–Whitney *U* test was conducted. The 0.05 level of significance was used for all statistical tests. All values were expressed as mean (SD).

RESULTS

There were no statistically significant differences between the two groups in patient characteristics (table I).

MAP decreased significantly in both groups after bolus injection of enoximone (group I: 11%; group II: 7%) compared with control values. A further marked and significant decrease in MAP was

TABLE I. *Characteristics of the patients receiving enoximone 0.5 mg kg^{-1} followed by the application of 1 MAC of either halothane or isoflurane (mean (range or* SD*)). Group I: enoximone followed by halothane* (n = *10)); group II enoximone followed by isoflurane* (n = *10)). BSA = body surface area*

	Group I	Group II
Age (yr)	61.3 (40–70)	63.2 (43–68)
Weight (kg)	72.4 (6.8)	73.9 (6.8)

BSA (m^2)	1.84 (0.11)	1.83 (0.13)

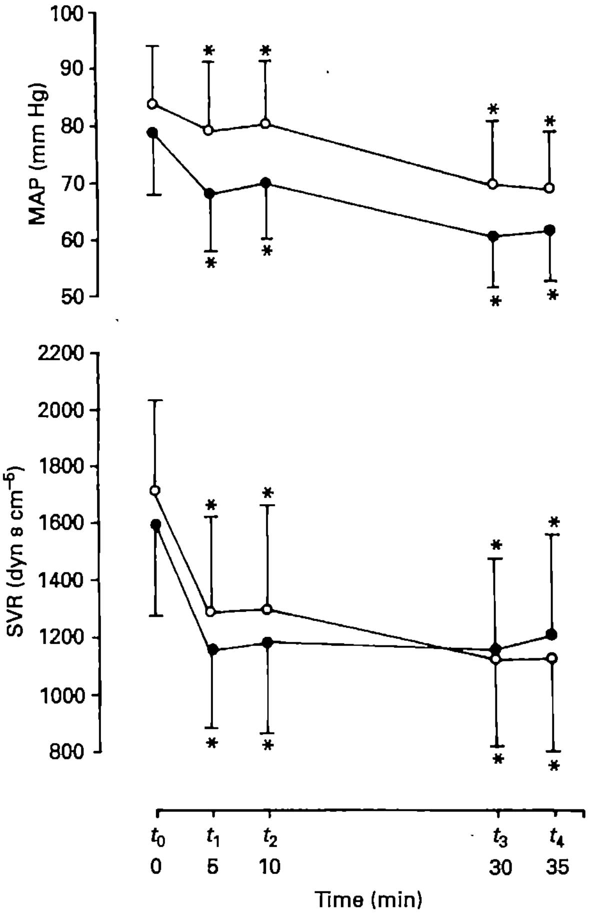

FIG. 2. Mean arterial pressure (MAP) and systemic vascular resistance (SVR) after bolus injection of enoximone 0.5 mg kg^{-1} (t_1, t_2) followed by the application of 1 MAC (steady state = t_3, t_4) of either halothane ($n = 10$) or isoflurane ($n = 10$) (mean, SD). ● = Enoximone followed by halothane; ○ = enoximone followed by isoflurane. *$P < 0.05$ compared with control.

observed with halothane (12%) and isoflurane (12%), respectively, in comparison with the values obtained with enoximone (fig. 2).

In both groups, SVR decreased significantly after administration of enoximone (26%, 24%) compared with control values. In the isoflurane group, there was a further moderate but significant decrease in SVR (10%) compared with values obtained with enoximone, whereas with halothane there was no further change (fig. 2).

Enoximone produced a significant increase in CI in both groups (25%, 27%) compared with the original control values. With isoflurane, CI remained essentially unchanged, while halothane decreased CI significantly by 20%, compared with the values after enoximone (fig. 3).

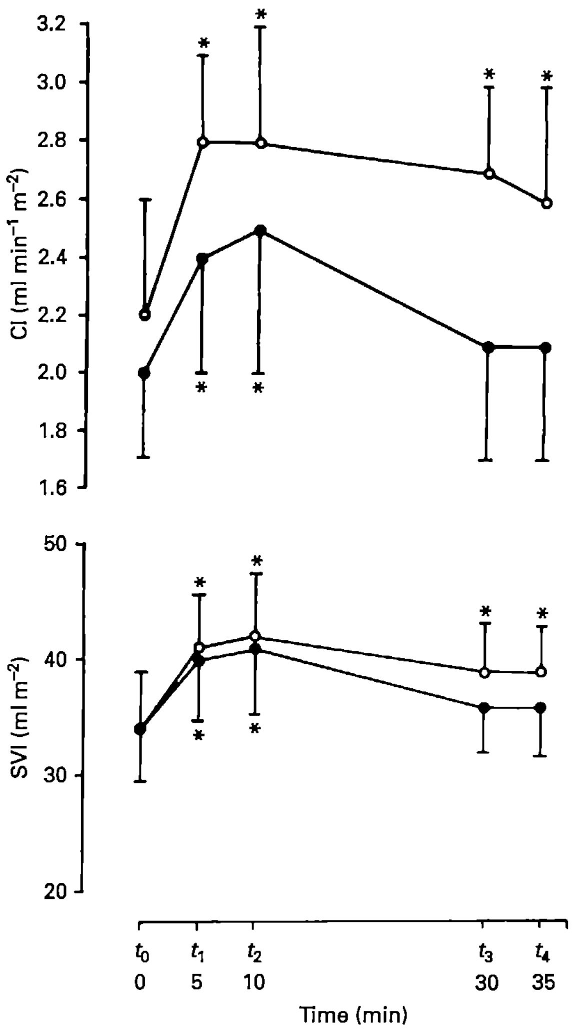

FIG. 3. Cardiac index (CI) and stroke volume index (SVI) after bolus injection of enoximone 0.5 mg kg^{-1} (t_1, t_2) followed by the application of 1 MAC (steady state = t_3, t_4) of either halothane ($n = 10$) or isoflurane ($n = 10$) (mean, SD). ● = Enoximone followed by halothane; ○ = enoximone followed by isoflurane. *$P < 0.05$ compared with control.

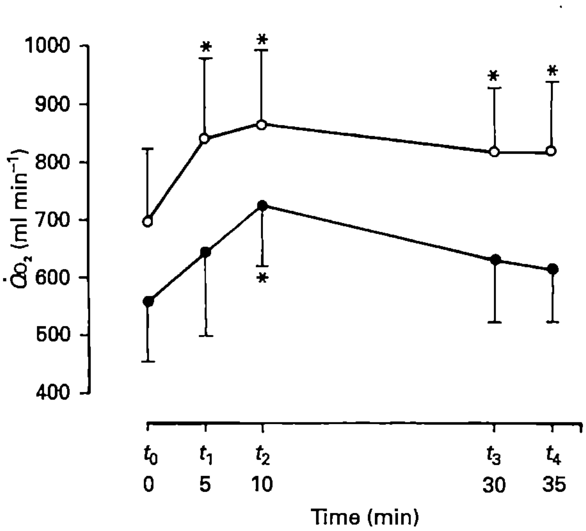

FIG. 4. Oxygen availability ($\dot{Q}o_2$) after bolus injection of enoximone 0.5 mg kg^{-1} (t_1, t_2) followed by the application of 1 MAC (steady state = t_3, t_4) of either halothane ($n = 10$) or isoflurane ($n = 10$) (mean, SD). ● = Enoximone followed by halothane; ○ = enoximone followed by isoflurane. *$P < 0.05$ compared with control.

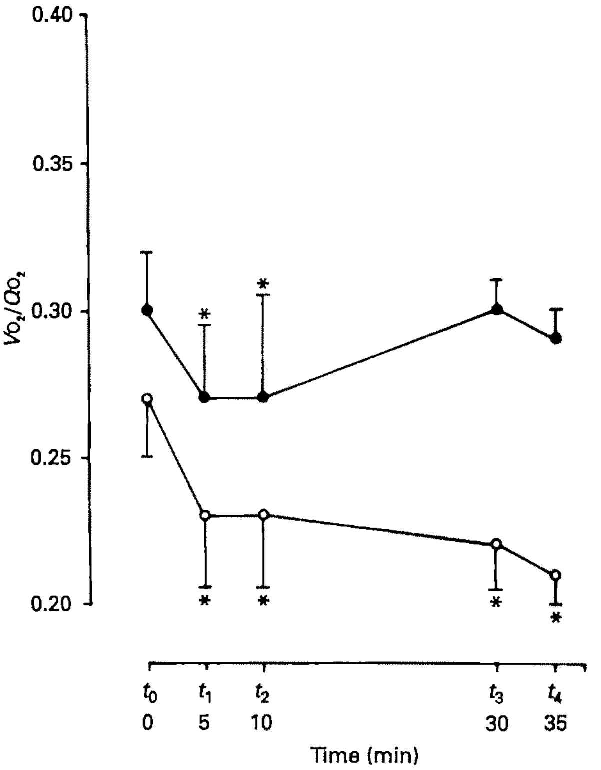

FIG. 5. Oxygen extraction rate $\dot{V}o_2/\dot{Q}o_2$ after bolus injection of enoximone 0.5 mg kg^{-1} (t_1, t_2) followed by the application of 1 MAC (steady state = t_3, t_4) of either halothane ($n = 10$) or isoflurane ($n = 10$) (mean, SD). ● = Enoximone followed by halothane; ○ = enoximone followed by isoflurane. *$P < 0.05$ compared with control.

A similar pattern was observed with SVI. After injection of enoximone, SVI increased significantly, by 21% in group I and 24% in group II, compared with control. With halothane there was a significant decrease in SVI (15%) in comparison with the values obtained with enoximone, whereas isoflurane had almost no effect (fig. 3).

$\dot{Q}o_2$ increased significantly after i.v. injection of enoximone in both groups (group I: 30%; group II: 23%) compared with control, decreased significantly after halothane (20%) compared with values obtained with enoximone, but remained essentially unchanged with isoflurane (fig. 4).

With enoximone, $\dot{V}o_2/\dot{Q}o_2$ decreased significantly in both groups (group I: 10%; group II: 15%) in comparison with control values. With halothane, it increased significantly (10%) compared with the values after enoximone and returned to control, whereas with isoflurane there was no change (fig. 5).

There were no statistically significant changes within groups or between groups in heart rate, filling pressures, pulmonary haemodynamics and oxygen consumption (table II).

With continuous ECG analysis, there were no changes in ST segments of more than 0.1 mV.

DISCUSSION

The cardiotonic effect of any drug results ultimately from an increase in the concentration of intracellular free calcium available to interact with the contractile proteins, an increased sensitivity of the myofilaments to calcium, or both [3]. Phosphodiesterase (PDE) inhibiting agents increase the amount of intracellular cyclic adenosine monophosphate (cAMP), thereby enhancing protein phosphorylation and subsequently increasing calcium availability at the myofilaments.

Enoximone, a specific PDE inhibitor, interacts with the PDE isoenzyme III, which is present in myocardial and vascular smooth muscles. This interaction leads to an increase in myocardial contractile performance and to a decrease in vascular smooth muscle tone—two effects which are demonstrated in our study: after injection of enoximone, there was an increase in CI and SVI, whereas SVR decreased markedly. The increases in CI and SVI were most probably caused by the positive inotropic effect of enoximone, resulting mainly from inhibition of cardiac PDE III, leading to an increase in myocardial cAMP content. However, some drugs with PDE inhibiting activity have a direct effect on myofibrils, by sensitizing them to Ca^{2+} and thus the myocardial force of contraction is increased independently of changing calcium concentrations [3]. This effect has been observed with other agents with PDE inhibitor actions (pimobendan and imidazodan), but it is unlikely to occur with the selective PDE agents currently available for clinical use [4, 5]. It has been reported previously that PDE inhibitors improve haemodynamic state in patients with acute heart failure after myocardial infarction [6, 7] and with low output syndrome after cardiac or general surgery [8–10].

In patients after coronary revascularization, the inotropic response of PDE inhibitors has been shown to be comparable to that of dobutamine, but the vasodilator activity of dobutamine may be greater [11, 12]. It has been proved, by *in vitro* studies [13] and after direct intracoronary injections [14], that PDE inhibitors used clinically possess positive inotropic activity.

Marked vasodilatation and the resulting decline in SVR after injection of enoximone, observed in the patients in our study, may be a result of increased cAMP content in vascular smooth muscle cells. Increased concentrations of cAMP lead to phosphorylation of the enzyme myosin light-chain kinase, thereby dephosphorylating myosin light chains, resulting in vasodilatation [3]. Smooth muscle relaxation is also mediated by cyclic guanosine monophosphate (cGMP), via cGMP-dependent protein kinases [15]. Cyclic GMP-mediated vasodilatation may have contributed to the marked decrease in SVR in our patients, as PDE III isoenzymes, although proved to be "high affinity cAMP PDE", also hydrolyse cGMP [16]. In isolated limb studies in resting patients with heart failure, SVR was mainly reduced in skeletal muscles [17–20].

In the present study, enoximone produced a marked decrease in MAP in all patients. This agrees with the findings of other investigators who showed that PDE inhibitors may lead to profound vasodilatation and hypotension [21]. Furthermore, it has been stressed that the pharmacodynamic effects of amrinone suggest predominant vasodilatation,

whereas the positive inotropic effect was less important [22]. It is questionable if this is true for enoximone. It is assumed that the relative contributions of the vasodilator and inotropic action of PDE inhibitors depend on the patient in specific clinical circumstances [3].

Enoximone has been shown to shorten atrial and atrioventricular node refractoriness and ventricular refraction [23]. These features enable enoximone to produce increases in heart rate and atrial or ventricular arrhythmias. In the present study, there was no evidence of increased atrioventricular node conduction or atrial or ventricular refraction shortening, as heart rate remained unchanged and arrhythmias did not occur. Other investigators showed that milrinone [24] and amrinone [25] are associated with either no change or an increase in ventricular arrythmias.

The reduction of mean arterial pressure in our patients may have compromised coronary artery perfusion. It has been shown that there is a reduction of regional coronary vascular resistance with PDE inhibitors [26, 27], resulting in increased myocardial perfusion. Coronary vasodilatation may induce intracoronary steal, but there has been no clinical evidence of myocardial ischaemia with PDE inhibitors. In patients with proven coronary artery stenosis undergoing ventricular pacing studies, i.v. enoximone has been shown to increase the anginal threshold while left ventricular stroke work index was maintained [28]. Furthermore, PDE inhibitors have been shown to increase cardiac index without compromising the myocardial supply to demand ratio [29]. In our patients, there were no changes in ST levels indicative of myocardial ischaemia, although this does not exclude imbalance in myocardial oxygen supply to demand.

The observations made after administration of the volatile anaesthetics largely confirm the well known cardiovascular effects of halothane and isoflurane. In summary, we found that heart rate remained unchanged with halothane; MAP was reduced by halothane and isoflurane; SVR decreased with isoflurane, but was not affected by halothane; SVI declined with halothane; and CI and $\dot{Q}O_2$ decreased and $\dot{V}O_2/\dot{Q}O_2$ increased with halothane.

Some results were not consistent with previous knowledge of the effects of volatile agents. After i.v. enoximone, heart rate remained unchanged with isoflurane; SVI essentially remained unchanged with isoflurane; and CI, $\dot{Q}O_2$ and $\dot{V}O_2/\dot{Q}O_2$ were almost not affected with isoflurane.

Our data indicate that, under the influence of enoximone, the mechanisms of action responsible for circulatory depression differ with halothane and isoflurane. While isoflurane appears to cause a reduction in MAP primarily by vasodilatation, halothane acted primarily by myocardial depression.

In conclusion, our results suggest that, in contrast with halothane, isoflurane enhances the vasodilator action of enoximone, and that halothane attenuates the positive inotropic action of enoximone to a far greater extent than isoflurane in patients with coronary artery disease.

ACKNOWLEDGEMENTS

We gratefully acknowledge the work of three members of our nurse staff, Christa Hölcker, Michael Trautmann and Jürgen Salamon who gave great support in performing this study.

REVIEW ARTICLE

THE VALUE OF PRE-EMPTIVE ANALGESIA IN THE TREATMENT OF POSTOPERATIVE PAIN

J. B. DAHL AND H. KEHLET

Our knowledge and understanding of the physiology of acute pain has improved in recent years. Most of this new information has been gathered from basic science and experimental studies. The recent papers by Wall [40] and Woolf [41] have stimulated much discussion on the potential clinical implications of this knowledge for the management of acute postoperative pain, and the concept of "pre-emptive analgesia" has gained widespread acceptance. This paper is a critical analysis of clinical studies on the effects of pre-emptive analgesia on acute postoperative pain.

BACKGROUND

Tissue injury results in disruption of the normal specialization of the CNS, with alterations in the processing of afferent stimuli [41, 42]. Experimental studies have demonstrated that peripheral injury may result in expansion of receptive fields and decrease in the threshold of dorsal horn neurones [13, 14, 41, 42]. This facilitation may be prolonged, depending on the stimulus and the type of afferents activated [41, 42]. Consequently, innocuous inputs may generate pain (allodynia), with increased pain to suprathreshold stimulation (hyperalgesia) and development of spontaneous pain [41, 42]. The neurophysiological and molecular mechanisms of these changes may involve an increase in synaptic efficacy of excitatory inputs or a decrease in inhibitory inputs [13, 42] mediated by wind-up [31], and neurokinin and N-methyl-D-aspartate (NMDA) receptor mechanisms [10, 14, 42]. Furthermore, changes in second messengers and gene expression may lead to prolonged functional changes in the nervous system [14].

In humans, cutaneous injury is followed by alterations in thermal and mechanical sensibility [19, 25, 26, 33]. "Primary hyperalgesia" refers to changes within the area of injury and "secondary hyperalgesia" to changes in the undamaged tissue surrounding the injury. Primary hyperalgesia is explained by sensitization of peripheral nociceptors [19, 25, 26, 33]. A recent series of elegant studies in humans and primates supported the suggestion that secondary hyperalgesia is caused by altered central processing of mechanoreceptive input from the periphery [2, 24, 25, 36, 38]. Based on these experimental and clinical studies, it has been proposed that surgical trauma in humans may lead to comparable alterations in sensory processing, resulting in amplification and prolongation of postoperative pain, and possibly persistent postsurgical pain [40–42].

To date, only four studies have investigated the effect of surgery on pain sensitivity in humans [7, 17, 18, 27]. Postoperative sensory thresholds were reported to be unaffected [17, 18] or increased [27], but in the latter study, only perception thresholds to electrical stimulation were investigated—not pain thresholds, which would have been more appropriate [27]. Recently, increased sensitivity and pain to noxious electrical stimulation in the A-β range were observed in patients after gynaecological surgery [7]. Furthermore, the threshold of the nociceptive flexion reflex was decreased in the early (48 h) postoperative phase [7]. These observations of allodynia and hyperalgesia in postoperative patients may be a result of postoperative sensitization of central neurones. However, no conclusion on the relative contribution of central sensitization to postoperative pain can be derived from these studies. Thus data demonstrating neuronal plasticity in postoperative patients are limited and the relative contributions of central sensitization to the intensity and duration of acute pain in humans have not been identified. No information is available on the degree or duration of noxious inputs required to induce central changes, or the question if postoperative pain itself may lead to alterations in dorsal horn excitability, independent of the afferent barrage during surgery. Finally, it is not known if the intensity and maintenance of postoperative pain is more dependent on central hyperexcitability than continuous afferent barrage from the wound.

"PRE-EMPTIVE ANALGESIA"

In experimental studies, acute pain behaviour or hyperexcitability of dorsal horn neurones may be eliminated or reduced if the afferent barrage is prevented from reaching the CNS by *pre*-injury neural block with local anaesthetics [4, 5, 44] or if

(Br. J. Anaesth. 1993; **70**: 434–439)

[39]	Wound infiltration LA	Inguinal herniorrhaphy	May be supportive, but other mechanisms than modulation of central hyperexcitability may be effective
[3]	Ileo-inguinal block + spinal anaesthesia	Inguinal herniorrhaphy	May be supportive, but other mechanisms than modulation of central hyperexcitability may be effective
[20]	Wound infiltration LA	Tonsillectomy	May be supportive, but other mechanisms than modulation of central hyperexcitability may be effective
[32]	Subdiaphragmatic LA	Gynaecological laparoscopy	May be supportive, but other mechanisms than modulation of central hyperexcitability may be effective
[34]	Extradural LA + morphine + systemic indomethacin	Cholecystectomy	Not supportive
[Unpublished]	Extradural LA + morphine	Mini laparotomy–cholecystectomy	Not supportive
Section III			
[21]	Extradural morphine	Trans-sternal thymectomy	Not supportive
[23]	High-dose systemic alfentanil	Abdominal surgery	Not supportive
[22]	Premedication	Lumbar disc prolapse surgery	Interpretation hindered by methodological deficiencies
Section IV			
[15]	Pre- and postoperative flurbiprofen	Oral surgery	Interpretation hindered by methodological deficiencies
Section V			
[1]	Extradural bupivacaine or opioid or combination	Lower limb amputation	Interpretation somewhat hindered by methodological deficiencies. Patients with *pre*operative pain cannot be extrapolated to other surgical procedures
[37]	TENS and extradural bupivacaine	Caesarean section	Interpretation hindered by methodological deficiencies

the excitability of the CNS is suppressed with opioids *before* it receives a nociceptive input [11, 43]. Similar antinociceptive procedures were less effective when applied *post*-injury [5, 11, 43, 44], although one study showed spinal anaesthesia 5 min after the injury also to be effective [4]. Consequently, the importance of "timing" of analgesia has been suggested to be of potential major importance in the treatment of postoperative pain [40–42].

Clinical studies of pre- *and* post*operative neural block or wound infiltration with local anaesthetics* (table I, section I)

Only three studies have been published comparing the postoperative analgesic effect of an identical neural block administered before or after the surgical stimulus [8, 12, 16]. Two studies compared the effect of *pre*- and *post*operative local infiltration with lignocaine on pain after inguinal herniorrhaphy [12, 16]. In one study, there was no difference in pain scores, but the time to first request for additional analgesia (non-steroidal anti-inflammatory drug (NSAID)/opioid) was increased in patients with preoperative infiltration of the surgical area compared with a similar postoperative block [16]. However, pain was evaluated for only 6 h after operation [16]. In the other herniorrhaphy study, there was no significant difference in times to first request for morphine, total morphine requirements or pain scores at rest or during physical activity, between patients with an inguinal field block performed before compared with after surgery. Patients were followed up for 7 days after operation [12]. In the third study, patients undergoing colonic surgery received either an extradural dose of 9 ml of bupivacaine 7.5 mg ml^{-1} plus morphine 2 mg before or after surgery, followed by low-dose continuous extradural bupivacaine 0.25 mg ml^{-1} plus morphine 0.2 mg ml^{-1} at a rate of 4 ml h^{-1} for 72 h [8]. The results showed no significant differences in pain scores at rest or during mobilization, or in request for additional morphine [8].

Thus, from these few studies, there is no firm evidence that timing of analgesic treatment—that is, pre-emptive analgesia—has important effects on postoperative pain or requirements for additional analgesics. Obviously, more studies in other procedures and with different pre-emptive analgesia regimens are required, and studies are needed to evaluate the effect of such regimens on the occurrence of very late (chronic) postoperative pain.

Preoperative neural block or wound infiltration with local anaesthetics compared with no treatment or placebo (table I, section II)

In a non-randomized, retrospective study, McQuay, Carroll and Moore [30] investigated patients undergoing a variety of surgical procedures on the extremities and receiving either *pre*operative opioids or no premedication, a variety of local anaesthetic blocks, or both. The results showed that median time to first request for postoperative analgesia was prolonged significantly by opioid premedication, by a local anaesthetic block and by a combination of premedication and a local anaesthetic block, with increased analgesic efficacy in that order. However, this non-randomized study in badly defined analgesic techniques and patients did not address the question of the value of pre-emptive analgesia (that is, timing of analgesia *per se*) and the design of the study prevents interpretation in this context.

In a prospective, randomized study, preoperative incisional local anaesthetic combined with general anaesthesia in patients undergoing inguinal herniorrhaphy was compared with general anaesthesia alone and with spinal anaesthesia [39]. The study is outstanding, as pain at rest and mobilization, and wound tenderness were assessed by algometer. The study was well designed, with well defined postoperative additional analgesic treatment and only one surgeon, performing a well defined procedure. The results showed that *pre*operative incisional neural block provided superior and prolonged analgesia for 24 h and 48 h after operation, compared with general anaesthesia alone, while the spinal anaesthesia group had an intermediary analgesic response. The prolonged analgesic effects of incisional local anaesthetic obviously could be caused by reduction of central hyperexcitability, although this was not documented by the study, as a similar analgesic procedure applied after operation was not investigated. Another explanation for these positive findings could be reduction of the primary hyperalgesic response resulting from the well documented anti-inflammatory effects of local anaesthetics in *in vitro* and experimental studies [39].

In another study, *pre*operative spinal anaesthesia and percutaneous ileoinguinal nerve block were found to reduce postoperative pain for 48 h after herniorrhaphy compared with pain in patients operated under spinal anaesthesia only [3]. Pain was assessed only at rest and interpretation is somewhat hindered by a badly defined additional analgesic treatment with different drugs, although it was stated that the overall need for additional analgesics was reduced in the combined spinal–inguinal block group [3]. Again, this study may support the concept that *pre*operative neural block may reduce late *post*operative pain in small scale surgery, but a similar analgesic procedure applied after operation was not studied.

A study in 14 patients, aged 6–18 yr, undergoing tonsillectomy demonstrated that 0.25 % bupivacaine 3 ml/tonsil significantly reduced the constant pain score for 6 days compared with a saline control group. Pain on swallowing was also reduced significantly by the preoperative block for up to 10 days after operation [20]. Surgery was undertaken by the same surgeon and treatment blinded for the assessor of pain. Postoperative pain was treated with paracetamol, apparently with the same dosing regimen in both groups. Again, these very positive results may be explained by reduction of central hyperexcitability as in the study by Tverskoy and colleagues [39], but an effect mediated by reduction of primary hyperalgesia from the anti-inflammatory effects of bupivacaine cannot be excluded.

In a study in patients undergoing day-case laparoscopy, 80 patients were allocated randomly to initial subdiaphragmatic administration of 0.25 % bupivacaine 80 ml, 1 % lignocaine 80 ml with adrenaline, saline 80 ml or no peritoneal administration [32]. Pain scores at rest were reduced significantly in the local anaesthetic treatment groups compared with the non-treatment groups for up to 48 h after operation. Although no information was given on postoperative additional analgesics in this study, the results again may support the concept of pre-emptive analgesia and reduction in central hyperexcitability, although this was not proven, and an effect on peripheral nociceptors caused by anti-inflammatory effects cannot be excluded.

In two randomized, but not double-blind studies in patients undergoing classical cholecystectomy [34] or laparoscopic cholecystectomy [unpublished observations] (who recieved intensive *pre*operative extradural analgesia with 0.5 % or 0.75 % bupivacaine combined with *pre*operative extradural morphine followed by continuous extradural combined bupivacaine and opioid treatment), the initial extremely effective analgesia during rest, cough and mobilization did not result in prolonged pain relief during physical activity, when the initial block disappeared. These two studies document clearly that clinically relevant and very effective extradural analgesic regimens, even when administrated before operation, have no important effect on later postoperative pain during physical activity and therefore do not suggest that pre-emptive analgesia, even when combined with relatively prolonged postoperative analgesia, "prevents" or reduces late postoperative pain.

Pre-emptive anaesthesia with opioids (table I, section III)

In one randomized, placebo-controlled double-blind study in patients undergoing trans-sternal thymectomy, preoperative extradural morphine 7 mg compared with saline had no effect on postoperative pain scores at rest or on additional analgesic requirements beyond the initial 8-h postoperative period [21]. However, the study was small including only 19 patients. In another randomized, placebo-controlled study, a *pre*operative bolus of alfentanil 30 μg kg^{-1} followed by an intraoperative infusion of 40 μg kg^{-1} h^{-1} had no effect on *post*operative pain scores or requirement for additional opioids [23]. These two studies [21, 23], therefore, do not support experimental studies with minimal trauma [11, 43] to suggest that *pre*injury administration of opioids can reduce *post*operative pain.

Finally, a non-randomized study in patients undergoing lumbar disc prolapse surgery and receiving a variety of premedicant drugs, concluded that additional opioid premedication reduced time to first demand for a postoperative analgesic and the overall need for postoperative analgesia [22]. Because of major methodological deficiencies and differences in sex distribution and with the finding that women required more analgesics than men, this study is unable to make the conclusion that "it is confirmed that opiate premedication diminishes the sustained hyperexcitability of the central nervous system caused by intraoperative stimuli" [22].

Pre-emptive analgesia with NSAID (table I, section IV)

Only one study has examined combined *pre-* and *post*operative NSAID (flurbiprofen) compared with *post*operative flurbiprofen alone on postoperative analgesia after removal of the third molar [15]. The results suggested that the combination was more effective, which is not unexpected, as the total dose of NSAID was larger in the combined treatment group, and therefore the results cannot be taken as an argument for increased efficacy of pre-emptive analgesia compared with *post*injury treatment.

Other studies (table I, section V)

In the discussion on the potential clinical importance of pre-emptive analgesia, the studies by Bach, Noreng and Tjellden [1] and Smith and colleagues [37] have been used to support the hypothesis of a preoperative neural block reducing central hyperexcitability, postoperative pain and analgesic requirements [6, 40]. The former study [1] in 26 patients undergoing limb amputation allocated randomly to *pre-* and *intra*operative extradural block or *intra*operative block alone, assessed the occurrence of phantom limb pain for the subsequent 12 months. Only patients with preoperative pain were included, but pre- and postoperative pain scores in the two groups were not presented. There was no information on the extradural regimen, except that it was provided for 3 days by extradural morphine or 0.25% bupivacaine or a combination, aiming at freedom from pain, although this was not assessed or documented. The authors stated that patients who continued to have pain despite the *pre*operative extradural block were excluded from further investigation, but no information was given on the number of patients excluded. However, apparently no patient was excluded [M. Noring, personal communication]. Extradural analgesia was not given after operation in any group. The results showed a significant reduction in phantom limb pain 6 months after operation, with a non-significant similar trend 7 days and 1 yr after operation. The degree of phantom limb pain was not presented. Although very interesting, great care should be taken in the interpretation of this study, because of several inadequacies in its design, and the results cannot be extrapolated to patients undergoing elective surgery who have no preoperative pain. However, despite this criticism, the study has stimulated much constructive debate on pre-emptive analgesia and the potential impact of such treatment on the occurrence of *late* and *chronic*, postoperative pain. Obviously, further well designed studies are required to answer this important and clinically relevant question.

A study [37] quoted to support the efficacy of pre-emptive analgesia [6, 40] considered 18 women undergoing elective Caesarean delivery, nine patients receiving transcutaneous electrical nerve stimulation (TENS) and nine placebo stimulation. In addition, and confounding for the interpretation, some of the patients received extradural anaesthesia and some general anaesthesia; exact numbers receiving each were not given [37]. Exact pain data were not presented, but it was mentioned that a non-significant reduction in constant and movement-associated incisional pain was found in the TENS treated women in the extradural group, and that the placebo treated women had significantly less movement-associated pain when receiving extradural analgesia. Obviously, these results in small groups of patients, together with a combination of different analgesic treatments and without presentation of exact data, cannot be taken as an indication of extension of analgesic efficacy of a *pre*operative neural block into the *post*operative period.

COMMENTS AND CONCLUSIONS

Available data from the few studies of identical neural block techniques before compared with after operation have not documented clinically relevant differences in *post*operative analgesia or analgesic requirements. Several studies are available on *pre*operative neural block with local anaesthetics compared with no treatment and most studies have found a reduction in late postoperative pain, request for additional analgesics, or both, compared with no neural block [3, 20, 30, 32, 39]. However, these studies do not demonstrate that such effects result from optimal timing of analgesia or a reduction in central hyperexcitability by *pre*operative analgesic treatment. Other studies during greater surgical trauma (abdominal surgery) have not been able to show that intense *pre*operative extradural analgesia followed by 1–4 days continuous extradural treatment with combinations of local anaesthetics and opioids has any long-lasting effect on *post*operative pain during rest or mobilization compared with no neural block [34, unpublished observations].

The difference between the effect of pre-emptive analgesia on postinjury nociceptive processing in experimental studies and pain in clinical studies may have several explanations. Although central sensitization may contribute to postoperative pain in humans, surgical trauma differs from the conditioning stimuli applied in most experimental studies. Contrary to a well-localized thermal or chemical injury, or brief C-afferent stimulation, the afferent input to the CNS during and after surgery is prolonged and extensive, with mixed cutaneous, muscular and visceral components. Central sensitization may be generated not only during surgery, but also in the postoperative period, because of persistent inflammation and hyperalgesia at the wound site. Thus intraoperative nociceptive block may not be adequate to reduce postoperative sensitization of central neurones. Recently, we have demonstrated more efficient reduction in secondary hyperalgesia to a burn injury in volunteers by a pre-burn block compared with an identical post-burn block, thus confirming experimental studies [unpublished observations]. However, this difference was significant only as long as the block was clinically effective [unpublished observations]. Furthermore, conventional analgesic methods (local anaesthetics or opioids) may not provide total C-afferent block during surgery. Thus the negative studies of pre- *vs* postoperative identical neural block [8, 12] or preoperative extradural block *vs* no block [34, unpublished observations] may be explained by insufficient afferent block. Thus several studies have documented that such blocks were ineffective in inhibiting potentials evoked by peripheral electrical stimulation [9, 28, 29] or the inflammatory response to surgery [34, 35]. Therefore, the optimal intensity, the duration and the timing of analgesia to prevent alterations in dorsal horn neurones after tissue injury of greater magnitude than that studied experimentally [4, 5, 10, 43, 44], need further investigation before clinical recommendations of pre-emptive analgesia can be established.

In conclusion, more, well designed clinical studies are needed to evaluate the clinical implications of the findings of central hyperexcitability and long-lasting analgesic effects of a pre-injury neural block in experimental studies. The exciting developments in our understanding of the biochemistry involved in the processing of nociceptive stimuli, based upon experimental studies, undoubtedly will have a major impact on the future treatment of acute pain. Prevention of the functional changes in the central nervous system by "pre-emptive analgesia" or other techniques, is a fascinating working hypothesis, but the definition of pre-emptive analgesia with regard to duration compared with the duration of the peripheral stimulus should be evaluated. Future, well designed clinical studies may clarify the relative importance of effective pre-emptive analgesia, compared with continuous analgesic treatment during the period when nociceptive impulses are generated from the wound, or if a combination of such efforts may provide improved pain relief without significant side effects. Finally, the effect of such regimens on the incidence of postsurgical chronic and neuropathic pain should be explored.

Note added in proof: In a recent study by Katz and colleagues, extradural fentanyl $4\ \mu g\ kg^{-1}$ was more effective when administered before compared with 15 min after surgical incision in patients undergoing thoracic surgery [45]. However, pain scores and postoperative morphine consumption were reduced only at one of five assessments (at 6 h and from 12 to 24 h after operation, respectively) during a 48-h study period. Furthermore, the pre-emptive study group was older and included more females than the control group, both of which factors may result in less pain and opioid consumption. Thus this study does not present evidence for a clinically significant effect of pre-emptive administration of opioids on postoperative pain.

SHORT COMMUNICATIONS

COMPARISON OF NASAL CANNULAE WITH FACE MASK FOR OXYGEN ADMINISTRATION TO POSTOPERATIVE PATIENTS

K. M. NOLAN, J. A. WINYARD AND D. R. GOLDHILL

SUMMARY

Thirty postoperative patients were allocated randomly to receive oxygen by Hudson face mask at 4 litre min^{-1} (group I) or 2 litre min^{-1} (group II) via nasal cannulae. From 22:00 on the first night after operation, the position of the nasal cannula or face mask was observed for 8 h using video and oxyhaemoglobin saturation (Sp_{O_2}) recorded simultaneously. In group I the mask remained on and positioned correctly in five patients. In the 10 other patients it was removed a total of 28 times, 17 for nursing tasks, for a median time of 2 min 39 s (range 30 s to 7 h 40 min 40 s). In group II the nasal cannula was removed once in one patient for 16 min 38 s and eight times in another for a total of 1 h 18 min 7 s. Average Sp_{O_2} with mask on was 98% (range 96.1–99.9%), with mask off 95% (range 89.8–98.8%) and with cannula 97% (range 90.8–99.3%). We conclude that nasal cannulae are more likely to remain in position than face masks and maintain an adequate saturation in most patients. (Br. J. Anaesth. 1993; **70**: 440–442)

KEY WORDS

Equipment: face mask, nasal cannulae. Oxygen: postoperative administration.

Some patients experience episodes of hypoxaemia after abdominal surgery [1, 2] and supplementary oxygen by face mask may prevent these episodes [3]. However, in a previous study [4] we showed that a face mask is often removed for routine nursing tasks, and patients are frequently hypoxaemic during these periods of mask removal. When nasal cannulae are used, many nursing tasks, such as mouth care and temperature measurement, do not interfere with the delivery of oxygen. We therefore determined if nasal cannulae are more likely than face masks to remain positioned correctly and ascertained the effect of mask or cannula position on oxyhaemoglobin saturation (Sp_{O_2}).

METHODS AND RESULTS

After Ethics Committee approval and patient consent to video observation and pulse oximetry, 30 ASA I–III patients (six men) undergoing elective abdominal surgery were allocated randomly to two equal groups. Group I received oxygen by Hudson face mask at 4 litre min^{-1} and group II received oxygen 2 litre min^{-1} by nasal cannulae. In group I, mean age was 67 yr (range 47–82 yr) and mean weight 66 kg (range 49–102 kg). In group II, mean age was 50 yr (range 26–75 yr) and mean weight 72 kg (range 48–105 kg). Anaesthetic technique and postoperative analgesia were not standardized, but the majority of patients in each group (60–80%) received i.m. opioids. Correct placement of the mask or cannula was confirmed at the start of the 8-h period from 22:00 on the first night after operation and neither the patient nor the ward staff was aware of the purpose of the study. The technique used was identical to that of the previous study [4]. A video camera operating in ambient light was used to record the patient's face, the position of the mask or cannula and the time as indicated by a clock within the field of view. Sp_{O_2} was recorded with an Ohmeda 3700e pulse oximeter. The oximeter reading was sampled approximately every 15 s and the digital value placed into a computer spreadsheet. Patients were asked also if they found the mask or cannula comfortable, uncomfortable or a nuisance. The following were determined from review of the video recordings:

(1) The number of times that the nasal cannula or mask was removed or replaced and the associated events.

(2) The duration of time for which the cannula or mask was on or off.

(3) Changes in Sp_{O_2} with alterations in cannula or mask position.

In group I, the mask remained on continuously and positioned correctly in five patients. In the 10 other patients it was removed a total of 28 times (range 1–6 times per patient) and remained off for median time of 2 min 39 s (range 30 s to 7 h 40 min 40 s). In five patients on eight occasions, the mask was off for more than 10 min (median 54 min 47 s; range 13 min 26 s to 7 h 40 min 40 s). In group II, the nasal cannulae remained positioned correctly in 13 patients and were removed once in one patient for 16 min 38 s and eight times in the other for a total of 1 h 18 min 7 s (median 3 min 32 s; range 1 min 0 s to 50 min 8 s). One patient in group I had a lesser average Sp_{O_2} (85%) with the mask on than with it off

TABLE I. *Events associated with oxygen mask removal*

Event	Total times mask removed (No.)	Average (range) time mask off for this event (h:min:s)	Time mask off for this event (% of total)
Mouth care	13	0:01:49 (0:00:30–0:04:48)	2
Removed by patient	9	01:00:00 (0:01:46–07:40:40)	46
Temperature observation	4	02:17:24 (0:01:15–06:18:48)	46
Vomiting/retching	2	0:35:16 (0:02:01–01:08:31)	6

(91 %). This patient's Sp_{O_2} was satisfactory at the start of the study period when the mask was on. After the patient was turned, Sp_{O_2} decreased and remained less than 90 % for approximately 4 h, despite the mask being positioned correctly. The patient slept for part of this time and was examined also by a doctor who auscultated the chest. When the mask was removed, Sp_{O_2} increased and remained between 90 % and 95 % when the mask was again replaced. One possible explanation is that the mask may have become disconnected from the oxygen source when the patient was turned initially. The oxygen outlet was, unfortunately, not within the view of the video. This patient has been excluded from analysis of Sp_{O_2} values. In the other patients, mask removal resulted in a median decrease in Sp_{O_2} of 2 % (range 0–8 %). In the two patients in whom the nasal cannula became displaced, Sp_{O_2} decreased by 1.3 % in the patient with a single removal and by a median of 2.3 % (range 0–5.5 %) in the other patient. Average Sp_{O_2} with the mask on was 98 % (range 96.1–99.9 %) and with the mask off 95 % (range 89.8–98.8 %). Average Sp_{O_2} with the cannula on was 97 % (range 90.8–99.3 %). In the two patients in whom the cannulae were removed, average Sp_{O_2} were 92 % and 99 % with the cannulae on and 91 % and 95 % with the cannulae off. In group I, Sp_{O_2} was $\leqslant$ 89 % for 2.4 % of the study period and the mask was off for 99.5 % of this time. In group II, Sp_{O_2} was $\leqslant$ 89 % for 2 % of the study and the nasal cannulae were off for 0.7 % of this time. In group I, Sp_{O_2} was $\geqslant$ 95 % for 87 % of the study time and the mask was on for 97.9 % of this time. In group II, Sp_{O_2} was $\geqslant$ 95 % for 82.6 % of the study time and cannulae were on for 100 % of this time. The events associated with mask removal are shown in table I.

The mask was removed for mouth care and temperature measurement on 17 occasions and accounted for approximately 50 % of the total time that the mask was off. The nasal cannulae were removed once for mouth care, seven times by the patient and once for the patient to get out of bed.

COMMENT

Hypoxaemia is a frequent occurrence in the 24 h after abdominal surgery [1, 2]. Supplementary oxygen by face mask can prevent these episodes of hypoxaemia [3]. However, in a previous study we observed that patients do not always receive the oxygen prescribed because the mask is often removed for routine nursing tasks such as mouth care and temperature measurement [4]. In this study, we have shown that nasal cannulae are more likely to remain in position than face masks. They do not have to be removed for mouth care and oral temperature measurement and can remain *in situ* during retching and vomiting. The duration of time that the mask remained off for nursing care was variable, ranging from 30 s to 6 h 18 min 48 s and accounted for approximately 50 % of the total time that the mask was off. Patient removal accounted for most of the remaining time that the mask was off. This was not reflected in the patients' assessment of mask comfort, as no patient found the mask uncomfortable, although 13 % of patients thought it a nuisance.

This study was carried out on the same wards as our earlier work [4] in which the mask remained on continuously and positioned correctly in only one of 20 patients. The nursing staff were unaware of the purpose of the studies and the improvement seen in mask placement in the present study may reflect a growing awareness of the importance of administering oxygen after operation. Specific instructions on the importance of mask placement may further improve mask positioning and this is now being investigated.

The average Sp_{O_2} with the cannulae on was 97 % and the average Sp_{O_2} for each patient was always greater than 90 % (range 90.8–99.3 %), so we can conclude that oxygen administered via nasal cannulae maintained an adequate Sp_{O_2} in the majority of patients. Previous work has shown that face masks, nasal catheters and nasal cannulae prevent postoperative hypoxaemia with equal success and that there is no significant difference between nasal cannula and mask [5]. The percentage of oxygen delivered to our two groups was not identical, but probably reflected clinical practice. An oxygen flow of 2 litre min^{-1} via mask or nasal catheter delivers a mean oropharyngeal oxygen concentration of 28 % and at 4 litre min^{-1} a mean concentration of 38 % [6]. Sixty percent of patients found the nasal cannula comfortable and 87 % of patients said the mask was comfortable. The cannulae used were simple plastic nasal prongs and the addition of a foam collar at the anterior nares, as described in a previous study [6], may increase patient acceptability. This study confirms that administering oxygen by face mask is unreliable. Nasal oxygen is of no benefit in patients with obstructed nasal passages. We did not attempt to assess nasal patency in our patients and nasal cannulae proved to be an effective way to deliver oxygen. They are cheaper than most masks and are acceptable to the majority of patients.

RELATIONSHIP BETWEEN VOLUME OF DISTRIBUTION OF ATRACURIUM AND BODY WEIGHT

C. J. R. PARKER AND J. M. HUNTER

SUMMARY

We have determined the central and steady state volumes of distribution of atracurium 0.25 mg kg^{-1} in 41 healthy adult patients. Volume of distribution, corrected for body weight (ml kg^{-1}), correlated negatively with body weight ($r = -0.612$ for central volume of distribution; $r = -0.737$ for the steady state volume of distribution). When expressed as an absolute volume, neither central nor steady state volume of distribution correlated significantly with body weight ($r = 0.120$ and $r = 0.131$, respectively). These data cast doubt upon the necessity for the dose of atracurium to be related to body weight in the healthy adult population. (Br. J. Anaesth. 1993; **70**: 443–445)

KEY WORDS

Neuromuscular relaxants: atracurium. Pharmacokinetics: body weight.

It is usual to administer non-depolarizing neuromuscular blocking drugs in a dose related to body weight, and to express volume terms in a pharmacokinetic analysis as a ratio to body weight, for example in the units ml kg^{-1}. It has been shown, however, that for pancuronium the volume of distribution is not correlated closely with body weight [1]. Beemer, Bjorksten and Crankshaw [2] reported the volume of distribution of atracurium at steady state during an i.v. infusion given to a series of 20 patients, and noted that the variability within the population increased when the estimates were "corrected" for total body weight.

The question arises as to the nature of the relationship between volume terms in the description of atracurium pharmacokinetics, and body weight. The aim of the present study was to describe the relationship between volume of distribution of atracurium and body weight in healthy adults, who were studied as part of a project to determine the relationship between the pharmacokinetics and pharmacodynamics of atracurium.

METHODS AND RESULTS

Patients and anaesthesia

We studied 41 healthy patients undergoing minor surgery requiring the use of neuromuscular blocking drugs. The study was approved by the Ethics Committee of the Royal Liverpool Hospital and informed consent was obtained from all patients, who were studied in three groups, which differed only in the technique used to maintain anaesthesia.

The physical characteristics of the patients are summarized in table I. Other results from 38 of these patients have been reported previously [3]; the present series included three others in addition, in whom electromyographic recordings were technically unsatisfactory.

Premedication consisted of either promethazine 50 mg or diazepam 10 mg, orally on the night before surgery, or cyclizine 37.5–50 mg with morphine 7.5–10 mg i.m. 1 h before surgery. Premedication was omitted in those patients admitted to hospital on the day of surgery.

Anaesthesia was induced with fentanyl 25–200 µg and thiopentone 250–500 mg, and maintained with 66% nitrous oxide in oxygen. In group one this was supplemented with 0.9% isoflurane end-tidal; in group two supplementation was with 0.5% halothane end-tidal; in a third group no volatile anaesthetic agent was used, but midazolam 3–10 mg i.v. was given. End-tidal concentrations of volatile anaesthetic agents were monitored using an infra-red analyser (Datex Normac).

After induction of anaesthesia, electromyographic monitoring of the adductor pollicis of one hand was undertaken with a Medelec MS6. Two i.v. cannulae were sited: one for withdrawal of blood samples, the other for administration of atracurium.

After a period of 20 min during which the end-tidal concentration of volatile anaesthetic agent (if used) was stabilized, atracurium 0.25 mg kg^{-1} was given by constant rate infusion over a period of 10 min. Ventilation was controlled and the trachea intubated when appropriate; end-tidal carbon dioxide partial pressure was maintained in the range 4.0–5.3 kPa (Datex Capnomac). Pharmacological antagonism of neuromuscular block was not used.

Measurement of plasma concentrations of atracurium

Heparinized blood samples (2.5 ml) were taken before and at 1, 2, 4, 6, 8 and 10 min after the start of the infusion, and at 1, 2, 4, 6, 8, 10, 15, 20, 25, 30,

40, 50, 60, 75 and 90 min after the end of the infusion. The plasma was frozen rapidly and stored at −20 °C until subsequent analysis by HPLC, using the method described in detail previously [3]. Plasma concentrations were measured in duplicate, with a coefficient of variation typically less than 6 % (range 1.6–11.1 %).

Data analysis

In order to obtain an estimate of the central volume of distribution, equations arising from a two-compartment pharmacokinetic model with elimination from both compartments were fitted to the plasma concentration profile using non-linear, least squares regression. The Gauss–Newton algorithm was used to define the least squares solution, with each datum point weighted as its inverse. The fit was implemented by a program written by the authors in Microsoft "Quickbasic" v4.0, and run on an 8086-based IBM-compatible personal computer. A two-compartment model was preferred to a simpler one-compartment model in all cases using the F test of residual variance (values of F ranged from 19.1 (2, 37 d.f.) to 1193 (2, 38 d.f.)). The individual rate constants of a two-compartment model with elimination from both compartments are not identifiable; the following combination of parameters was identified:

V_1 = central volume of distribution
α = hybrid distribution rate constant
β = hybrid elimination rate constant
$k_{21}+k_{20}$ = sum of exit rate constants from the peripheral compartment.

In order to obtain a measure of total volume of distribution, the steady state volume of distribution (Vd^{ss}) was estimated using the standard non-compartmental formula [4]:

$$Vd^{ss} = \left[\frac{\text{infused dose}}{\text{AUC}}\right] \cdot \left[\frac{\text{AUMC}}{\text{AUC}} - \frac{T}{2}\right]$$

where AUC = area under the curve; AUMC = area under the first moment curve.

Linear correlations were evaluated with Pearson's product–moment correlation coefficient.

The profile of mean plasma concentration for 38 of the 41 patients has been illustrated previously [3].

The mean central and steady state volumes of distribution, for each group are shown in table I, as absolute values. The central volume of distribution, expressed as an absolute volume (in litre) is plotted against body weight in figure 1. There was no significant correlation ($r = +0.120, n = 41, P > 0.1$).

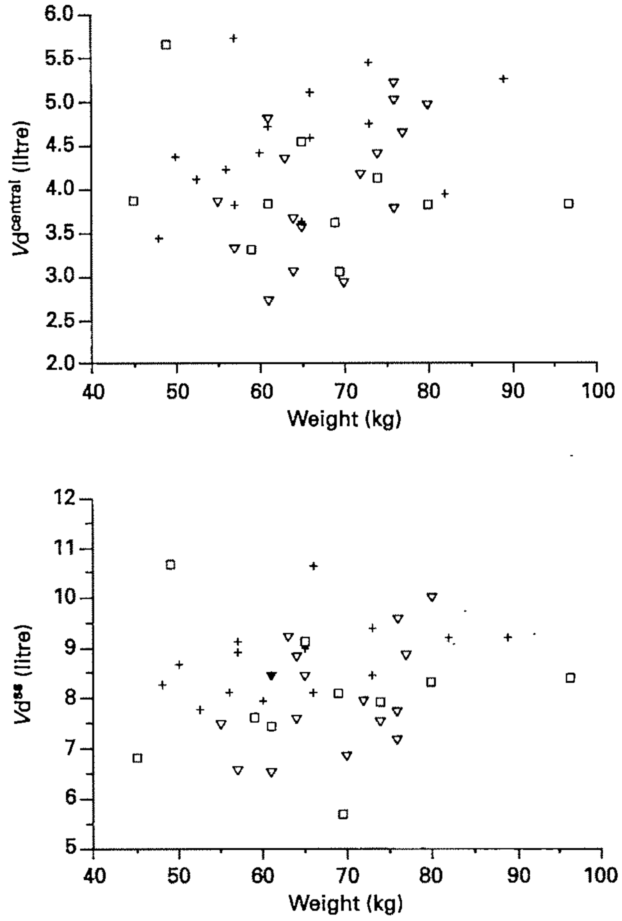

FIG. 1. Volume of distribution (in litre) plotted against body weight for isoflurane (+), halothane (▽) and midazolam (□). Upper panel: central volume of distribution; lower panel: steady state volume of distribution. No significant correlation is evident between each measure of volume of distribution and body weight ($r = +0.120$ for central volume of distribution; $r = +0.131$ for steady state volume of distribution).

Similarly, the steady state volume of distribution (expressed in litre) did not correlate significantly with body weight ($r = +0.131, n = 41, P > 0.1$) (fig. 1).

When the central and steady state volumes of distribution were normalized for body weight (units ml kg^{-1}) there was a highly significant negative correlation of both measures of volume of distribution with body weight: central volume of distribution $r = -0.612$, $P < 0.0001$; steady state volume of distribution $r = -0.737$, $P < 0.0001$.

COMMENT

Although the pharmacokinetics of atracurium have been studied extensively in the adult patient, the volume of distribution (the ratio of the amount of drug present to the plasma concentration) has generally been expressed in the units ml kg^{-1}. This practice can be justified only if the volume of distribution is proportional to body weight. It has been noted, within one population studied by Beemer, Bjorksten and Crankshaw [2], that the variance of the estimated steady state volume of distribution is increased on division of the absolute volume by body weight.

The present results are similar to those obtained for pancuronium by McLeod, Hull and Watson [1], who showed that volume of distribution, estimated by either V^{β} or V^{ss}, did not correlate significantly with body weight. The negative correlations between volume of distribution in ml kg^{-1} and weight presently reported simply represent the negative correlation of weight with its inverse. Their strength does, however, emphasize that the use of an inappropriate correction for body weight complicates rather than simplifies the comparison of results from subjects of differing weights. It is possible that this may have reduced the power of previous studies in which the volumes of distribution of groups of subjects were compared on an ml kg^{-1} basis.

Clearly, the present results apply only within the adult range in which they were obtained. Some relationship between body size and volume of distribution presumably exists in children but, although Brandom and colleagues were careful to consider an appropriate correction for body size in this group [5], it is not clear that this should be body weight. Indeed, volume terms were more nearly comparable between infants and children when comparison was based on body surface area.

One corollary of the present finding is that, if atracurium is administered in a dose related to body weight (that is, a fixed mg kg^{-1} dose), a relatively greater plasma concentration may be produced in heavier than in lighter adults; presumably, the drug may therefore achieve a greater effect. In a retrospective study in which the dose requirement for tubocurarine was judged on clinical grounds [6], Dundee showed that the dose administered during the first 2 h of anaesthesia was not related closely to body weight. Furthermore, division of the dose given by body weight did not diminish significantly the interindividual variability in the dose given.

The finding that the volume of distribution is independent of body weight is consistent with the water solubility of the drug and the fact that at least some of the variation in body weight between healthy adults is a result of variation in adiposity. The result cannot be extrapolated to more lipophilic drugs.

In retrospect, it would have been desirable to have assessed the physique of the present series of patients more thoroughly, for example with the use of skinfold thickness, to ascertain if it is possible to derive an index of body size which is related closely to the volume of distribution of atracurium. It does, however, remain clear that body weight is an unsuitable measure.

PIPECURONIUM-INDUCED PROLONGATION OF VECURONIUM NEUROMUSCULAR BLOCK

I. SMITH AND P. F. WHITE

SUMMARY

*We have examined the prolongation of a maintenance dose of vecuronium after an intubating dose of pipecuronium in 45 patients who received either pipecuronium 70 µg kg^{-1} or vecuronium 200 µg kg^{-1} i.v. for tracheal intubation, followed by either pipecuronium 10 µg kg^{-1} or vecuronium 15 µg kg^{-1} for maintenance of neuromuscular block. The duration of the vecuronium maintenance dose was greater after pipecuronium (40 (*SD *12) min) than after vecuronium (29 (9) min) (*P = 0.02*). The duration of pipecuronium after pipecuronium (49 (15) min) was similar to that of vecuronium after pipecuronium. We conclude that the duration of action of vecuronium is prolonged by prior administration of pipecuronium.* (Br. J. Anaesth. 1993; **70**: 446–448)

KEY WORDS

Neuromuscular relaxants: pipecuronium, vecuronium. Neuromuscular transmission: prolongation.

Pipecuronium bromide (Arduan) is a new non-depolarizing neuromuscular blocking drug, structurally similar to both vecuronium and pancuronium. Pipecuronium is comparable in duration of action to pancuronium, but is devoid of vagolytic actions [1]. Because of this long duration, anaesthetists might consider changing to a shorter acting neuromuscular blocker for subsequent maintenance doses—possibly vecuronium because it has cardiovascular properties similar to those of pipecuronium [1]. As the action of vecuronium is prolonged significantly after pancuronium [2, 3], we have examined the interaction between pipecuronium and vecuronium during balanced anaesthesia.

METHODS AND RESULTS

After approval by the Washington University School of Medicine Human Studies Committee, we studied 50 patients who gave informed consent. Healthy, ASA I or II patients, aged 18–65 yr were allocated to one of three groups according to a computer-generated random number sequence. Group 1 received pipecuronium for intubation and maintenance of neuromuscular block, group 2 received pipecuronium and then vecuronium, and group 3 received vecuronium throughout. Exclusion criteria included a body weight 30% greater than ideal values, chronic antibiotic therapy, neuromuscular disorders and abnormal reactions to myoneural blocking drugs.

All patients received midazolam 1–5 mg i.v. (for sedation and anxiolysis) before operation. Anaesthesia was induced with sufentanil 0.5–1.0 µg kg^{-1} and thiopentone 2–4 mg kg^{-1} i.v. Neuromuscular activity was monitored by electromyography (EMG) (NMT monitor 221, Datex medical instrumentation, Tewksbury, Massachusetts). Silver–silver chloride adhesive gel electrodes (AMI 1750, Medtronic, Andover Medical, Haverhill, Massachusetts) were applied as described previously [4], with the recording electrode over the body of the first dorsal interosseous muscle and the reference electrode over its insertion. Baseline measurements were obtained after loss of consciousness. The distal ulnar nerve was stimulated with a supramaximal (70-mA) square wave of 100 µs duration at 2 Hz, every 20 s. Groups 1 and 2 received pipecuronium 70 µg kg^{-1} i.v., and group 3 received vecuronium 200 µg kg^{-1} i.v.

Anaesthesia was maintained with a variable rate infusion of sufentanil 0.2–0.5 µg kg^{-1} h^{-1} and 60–70% nitrous oxide in oxygen. Isoflurane 0.2–0.5% (end-expired) was added to maintain haemodynamic stability (mean arterial pressure within 20% of pre-incisional value). Additional neuromuscular blocker was administered when the first twitch (T1) of the train-of-four returned to 25% of baseline: group 1 received pipecuronium 10 µg kg^{-1}, and groups 2 and 3 received vecuronium 15 µg kg^{-1}. Additional maintenance doses were administered when T1 again returned to 25% of baseline. Heart rate, non-invasive arterial pressure, end-tidal carbon dioxide partial pressure and volatile agent concentration, and oesophageal and peripheral temperatures were monitored continuously.

After discontinuation of sufentanil and isoflurane, residual neuromuscular block was antagonized with edrophonium 1 mg kg^{-1} and atropine 7–10 µg kg^{-1} i.v. Baseline drift was defined as failure of T1 to return to $\geqslant 80\%$ of the value before block, after adequate antagonism of the neuromuscular block (T4/T1 > 70%).

Weight (kg)	75 (11)	77 (12)	72 (9)
Height (m)	1.74 (0.06)	1.75 (0.11)	1.71 (0.06)
ASA physical status (I/II)	6/11	4/11	7/6
Sex (M/F)	11/6	11/4	8/5
Serum creatinine concn (mg dl^{-1})	1.0 (0.2)	0.9 (0.2)	1.0 (0.2)
Preoperative midazolam (mg)	2.4 (1.1)	1.9 (0.6)	2.6 (1.1)
Total sufentanil (μg)	149 (54)	171 (77)	139 (81)
Mean end-tidal isoflurane (%)	0.31 (0.14)	0.39 (0.11)	0.35 (0.13)
Mean end-tidal CO_2 (kPa)	6.0 (0.5)	5.9 (0.4)	5.7 (0.4)
Central temperature (°C)	36.2 (0.5)	35.9 (0.6)	35.8 (0.5)
Peripheral temperature (°C)	35.4 (1.0)	35.6 (0.6)	35.0 (1.4)
Median duration of procedure (min)	247 (105–518)	213 (175–499)	196 (113–373)
Median blood loss (ml)	750 (50–3000)	1025 (200–3000)	1000 (150–1400)
Median fluid replacement (ml)	4000 (1800–7900)	4100 (2450–7200)	4000 (1800–5200)

Data were analysed with the Stata statistical program, using analysis of variance for comparisons of continuous variables and chi-square test for discrete variables. Changes in continuous variables with time were analysed using paired t tests. Bonferroni's correction was applied to multiple comparisons. Data are expressed as mean (SD) (SE in graphs) unless stated otherwise. $P < 0.05$ was considered statistically significant.

Five patients were excluded from data analysis because of baseline drift. There were no significant differences in patient variables between the three groups (table I). Similarly, there were no differences in anaesthetic requirements or physiological factors likely to influence the duration of neuromuscular block (table I). Heart rate and arterial pressure did not differ between the groups at any time. Complete neuromuscular block was achieved after the intubating dose in all patients. The clinical duration (time for T1 to return to 25% of baseline) of the intubating dose of pipecuronium was 112 (36) min and 120 (33) min for groups 1 and 2, respectively, but only 89 (19) min for vecuronium ($P = 0.01$).

After pipecuronium (group 1), the duration of the first maintenance dose of pipecuronium was 49 (15) min. This was significantly greater than the duration of the first maintenance dose of vecuronium after vecuronium in group 3 (29 (9) min) ($P = 0.0004$). The duration of the same maintenance dose of vecuronium after pipecuronium (group 2) was significantly greater (40 (12) min) ($P = 0.02$) than that of vecuronium after vecuronium (group 3), and not significantly different from that of pipecuronium in group 1 ($P = 0.09$).

A subset of 12 patients (four, five and three in groups 1, 2 and 3, respectively) received multiple maintenance doses of neuromuscular blocking drugs. The duration of action (fig. 1) remained constant in patients receiving the same blocking drug for intubation and maintenance (groups 1 and 3). In contrast, when vecuronium followed pipecuronium (group 2), there was a significant, progressive decline in duration with each of the first three maintenance doses ($P = 0.03$). However, even after four maintenance doses, the duration was still significantly prolonged compared with group 1 (fig. 1).

COMMENT

When vecuronium is used after previous administration of pipecuronium, its effect is prolonged significantly and its duration of action becomes similar to that of pipecuronium (when administered in the manufacturer's recommended maintenance doses). This is consistent with the previously reported interaction between vecuronium and pancuronium [2, 3]. When T1 returns to 25% of baseline, 70–80% of receptors are still occupied by neuromuscular blocker, and the maintenance dose need occupy only the vacant receptors to suppress T1. As the majority of receptors remain occupied by the drug administered initially, the clinical duration depends more on the kinetics of the first drug than on those of the maintenance (supplementary) drug. With subsequent doses, a progressively smaller proportion of the receptor sites are occupied by the original neuromuscular blocker and the degree of prolongation of action should decline with time. After pancuronium, the first two maintenance doses of vecuronium were reported to be prolonged; however, this was negligible by the third dose [3]. After pipecuronium, we detected clinically significant prolongation after four vecuronium doses, although the number of patients in this subset was small. The clinical implication is that, when pipecuronium has been administered, there is no obvious benefit (in terms of shorter duration) in using vecuronium for maintenance of neuromuscular block.

We used the EMG in this study because of its simplicity, reliability and lack of susceptibility to patient position and mechanical factors. Evoked EMG correlates well with the results of force transduction in the assessment of neuromuscular

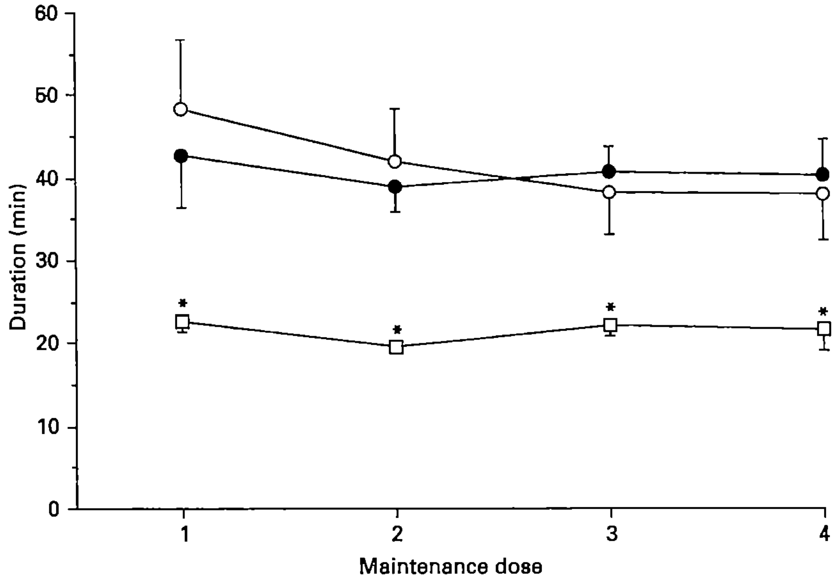

FIG. 1. Changes in the duration of action of maintenance doses of pipecuronium 10 μg kg^{-1} (group 1: ●, $n = 4$) or vecuronium 15 μg kg^{-1} (group 2: ○, $n = 5$; group 3: □, $n = 3$) over time (mean, SE). * $P < 0.05$ compared with groups 1 and 2.

block [4]. The major problem with the EMG is occasional failure of T1 to recover to baseline values (baseline drift), the mechanism of which is unknown [5]. We therefore excluded any patient in whom T1 did not return to within 20 % of baseline after antagonism of block with an anticholinesterase. Perioperative factors known to affect the duration of neuromuscular block or the accuracy of its measurement (e.g. carbon dioxide concentration and temperature) were similar in all three groups.

This study attempted to reflect the clinical conditions under which neuromuscular blocking drugs are frequently used. Doses were based on the manufacturer's recommendations, with the exception of the intubating dose of vecuronium, which was chosen in an attempt to achieve a duration of action approximately similar to that of pipecuronium 70 μg kg^{-1}. Although volatile anaesthetics may potentiate neuromuscular blocking drugs (for example, 0.9 % isoflurane decreases pipecuronium ED_{95} by 30 % [6]), the relatively small end-tidal concentration used in our study (0.35 (0.13) %) should have had minimal effects. Indeed, we found no correlation between duration of block and isoflurane concentration within the range used in this study.

In summary, pipecuronium was found to prolong the effect of subsequent doses of vecuronium such that standard maintenance doses of vecuronium and pipecuronium had similar durations of action. Although this potentiation decreased over time, it persisted for at least four maintenance doses. Consequently, there appears to be no advantage in using vecuronium as a maintenance agent after initial administration of pipecuronium.

ACKNOWLEDGEMENTS

We thank Robert M. Niecestro, PH.D., for his advice on the use of pipecuronium, Renee Johnson C.R.N.A., for her advice on the use of the Datex Relaxograph monitor and our research nurse, Linda Kratz, B.A.

EFFECT OF RADIANT HEAT ON THE METABOLIC COST OF POSTOPERATIVE SHIVERING

A. SHARKEY, R. H. GULDEN, J. M. LIPTON AND A. H. GIESECKE

SUMMARY

Hypothermia and postoperative shivering are uncomfortable and may be dangerous. This study demonstrates that postoperative shivering may be controlled quickly and effectively with radiant heat, thereby reducing oxygen consumption and increasing thermal comfort. (Br. J. Anaesth. 1993; **70**: 449–450)

KEY WORDS

Metabolism. Complications: shivering. Temperature.

Postoperative shivering occurs in a significant number of patients in modern recovery rooms and it may increase oxygen consumption by as much as 400% [1]. If the oxygen demand induced by postoperative shivering exceeds the ability of depressed respiratory and circulatory systems to deliver oxygen to tissues, a relative oxygen debt or "demand hypoxia" can result, placing poorly perfused tissues at risk of ischaemia.

When applied to the blush area (the face, neck and upper chest regions that have a high density of thermoreceptors and sensitivity to warmth) radiant heat was found to inhibit shivering in obstetric patients [2] and in healthy volunteers [3] without significant side effects. The present study was designed to determine the influence of such local application of radiant heat on the metabolic consequences of postoperative shivering.

METHODS AND RESULTS

After approval by the local institutional Review Board, we studied 19 visibly shivering patients who had undergone Caesarean section or tubal ligation (ASA I or II; ages 18–40 yr (mean 26.7 (SEM 1.4) yr); weight 55–96 kg (mean 73.9 (2.5) kg), body surface area 1.49–1.94 m^2 (mean 1.74 (0.3) m^2) after operation in the recovery room. Anaesthesia was performed under spinal block (seven radiant heat and three control patients), extradural block (one radiant heat, four control) or combined spinal–extradural block (three radiant heat, one control). All patients received Bicitra 15 ml orally 45 min before operation; and diazepam 10 mg orally was given to those patients undergoing tubal ligation. All nine Caesarean sections were performed under combined spinal–extradural or extradural anaesthesia using 0.75% hyperbaric bupivacaine 1.5–1.8 ml, followed by plain 0.5% bupivacaine 3 ml mixed with fentanyl 200 µg, injected into the extradural space via an indwelling catheter. All extradural catheters were removed after operation. Fentanyl 50–100 µg was administered i.v. after delivery to provide additional pain control. The remaining 10 patients underwent tubal ligation under spinal anaesthesia (5% lignocaine 70 mg in 7.5% glucose). All patients received fentanyl 50–100 µg i.v. during surgery.

By means of a table of random numbers, the shivering patients were allocated to receive either radiant heat or warmed blankets after operation. Each patient was covered with a canopy connected to a Deltatrac Metabolic Monitor (Sensormatic; Yorba Linda, CA) which continuously sampled expired gases and calculated oxygen consumption and carbon dioxide production. Arterial pressure, Sp_{O_2}, and ECG (lead II) were monitored continuously.

After 10 min of baseline observation, patients received either radiant heat or warmed blankets. Six infra-red bulbs (750 W) arranged in two rows were suspended 45 cm above the sternum to illuminate the blush region, which was covered with one layer of lightweight cotton cloth. Skin temperature was monitored constantly via dual thermistors applied to the chest, providing autofeedback regulation of power to the lamps; the temperature was maintained at 41 ± 0.1 °C to prevent thermal injury. After a 10-min warming period, the heat lamps were switched off and recordings were continued for an additional 10 min.

All data were subjected to statistical analysis using repeated-measure ANOVA and Tukey's protected t test (two-tail), with $P < 0.05$ considered significant. The two groups were not statistically different in weight, height, body surface area, age, anaesthetic or temperature on arrival in the recovery room. The absolute $\dot{V}o_2$ is shown in figure 1.

Baseline (shivering) oxygen consumption in the radiant heat and warmed blankets groups was not statistically different ($P > 0.05$). However, with the application of radiant heat, $\dot{V}o_2$ significantly de-

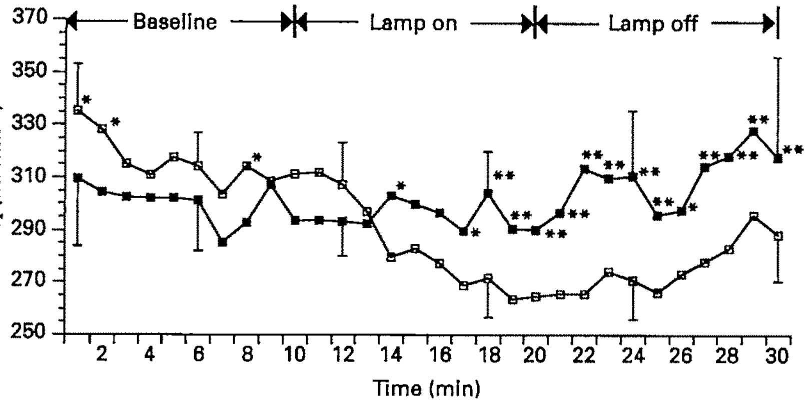

FIG. 1. Effect of radiant heat on postoperative oxygen consumption ($\dot{V}o_2$) in shivering patients. □ = Radiant heat group; ■ = control group. *$P < 0.05$; **$P < 0.01$ between groups.

creased ($P < 0.01$), whereas it remained increased in the warmed blankets group.

All radiant heat patients ceased visible shivering within 5 min of application of the heat and stated that they felt more comfortable. When the lamp was turned off, six of the eight patients resumed shivering and requested that the lamp be turned on again. Oxygen consumption increased in radiant heat patients, but did not return to baseline. All patients warmed with blankets complained of cold.

COMMENT

Intraoperative hypothermia was documented as a clinical entity more than 100 years ago [4]. Since then, many measures have been recommended to prevent heat loss during surgery and anaesthesia [5] but, despite this, the cold patient is still an "accepted concomitant" of postoperative recovery [6]. Such hypothermia is a primary factor in postoperative shivering.

Postoperative shivering may occur when the CNS temperature control systems emerge from anaesthesia and react to "cold" signals from thermoreceptors, which then initiate shivering, a thermogenic response.

Marked increases in oxygen consumption can occur in postoperative shivering, with an accompanying increase in postoperative morbidity and mortality. Our study demonstrates that postoperative shivering can be quickly and effectively controlled by warming the "blush" region and radiant heat. This treatment decreases oxygen consumption and, thus, reduces the immediate risks to cardiovascular and respiratory systems.

METABOLIC EFFECTS OF PROPOFOL AND FLUNITRAZEPAM GIVEN FOR SEDATION AFTER AORTIC SURGERY

F. MORITZ, J. PETIT, N. KAEFFER, G. OKSENHENDLER, H. PAPION, B. HECKETSWEILER, N. MOORE AND C. WINCKLER

SUMMARY

Sixteen patients who had undergone abdominal aortic surgery were allocated randomly to receive either propofol (total dose 3.2 (SEM 0.3) mg kg^{-1} h^{-1}) or flunitrazepam (total dose 15 (2) µg kg^{-1} h^{-1}) for 16 h after operation. Metabolic effects of sedation were assessed using a Deltatrac metabolic monitor. Initiation of sedation induced a 25% decrease in $\dot{V}O_2$ in both groups. The decrease was about 40% at 16 h. $\dot{V}O_2$ increased within 30 min after discontinuation of propofol and stabilized at values considerably less than the immediate postoperative value. A similar but slower increase was noted with flunitrazepam. While the propofol loading dose reduced the Buffington index and should therefore be avoided, no cardiovascular side effects were noted with the maintenance infusion. Weaning from ventilatory support was achieved within 15 (2) min and 264 (108) min after discontinuation of propofol and flunitrazepam, respectively. (Br. J. Anaesth. 1993; **70**: 451–453)

KEY WORDS

Anaesthetics, intravenous: propofol. Hypnotics, benzodiazepines: flunitrazepam. Metabolism: oxygen consumption. Recovery: postoperative sedation.

Oxygen consumption ($\dot{V}O_2$) increases after major surgical procedures in the early period of recovery from general anaesthesia [1, 2]. Short term sedation has been proposed to prevent the complications caused by this increase in $\dot{V}O_2$. Propofol can be used easily and safely in the ICU [2, 3]. However, it is not known if discontinuation of propofol, with subsequent brisk recovery, also induces a brisk increase in $\dot{V}O_2$.

This study was designed to compare metabolic and haemodynamic state during and after discontinuation of a 16-h postoperative sedation with either propofol or flunitrazepam.

METHODS AND RESULTS

After approval from the Institutional Ethics Committee and informed consent, we studied 16 ASA II–III stable patients who had undergone surgical treatment of infrarenal aortic aneurysm. Patients were allocated randomly to receive either propofol (group P) or flunitrazepam (group F) for 16 h, as soon as they responded to commands.

Anaesthesia had been induced with flunitrazepam 20 µg kg^{-1}, fentanyl 5 µg kg^{-1} and vecuronium 100 µg kg^{-1}, and maintained with intermittent administration of these agents combined with nitrous oxide and isoflurane.

Group P patients received an i.v. loading dose of propofol 2 mg kg^{-1} over 5 min followed by a continuous i.v. infusion of 3 mg kg^{-1} h^{-1}. In group F, the loading dose was flunitrazepam 0.02 mg kg^{-1} and the infusion 0.01 mg kg^{-1} h^{-1}. Boluses of drugs (propofol 1 mg kg^{-1} and flunitrazepam 0.015 mg kg^{-1}) were given to keep the patient at the required level of sedation (3–5 on Ramsay's scale). I.v. injections of morphine were allowed. Inotropic agents and vasodilators were given as required.

Ventilatory support was continued for the period of sedation, using a CPU 1 ventilator (Ohmeda Lab.). $\dot{V}O_2$, carbon dioxide production ($\dot{V}CO_2$) and respiratory quotient (RQ) were measured at the bedside using a Deltatrac metabolic monitor (Datex, Helsinki, Finland). After sedation was discontinued, the trachea was extubated if the following criteria had been met: total recovery, effective spontaneous breathing ($V_T > 10$ ml kg^{-1}, ventilatory frequency 10–25 b.p.m., $Pa_{O_2} \geq 10.7$ kPa and $Pa_{CO_2} \leq 6.7$ kPa), haemodynamic stability. Additional measurements were made using the canopy. Measurements were recorded immediately before sedation (T0), during sedation (at 30 min (T0.5) and 1 h (T1), 3 h (T3), 9 h (T9) and 12 h (T12)), immediately before discontinuation of sedation (T16 = TE) and for the following 2 h (TE+0.5, TE+1 and TE+2).

Measured $\dot{V}O_2$ was compared with the theoretical resting $\dot{V}O_2$ values, calculated using the Combes equations. Energy expenditure was calculated using the simplified Weir equation, and compared with the basal energy expenditure calculated using the Harris and Benedict equations. The rate–pressure product (RPP = HR × SAP; if greater than 12000, myo-

cardial ischaemic risk present) [4] and the Buffington index (BI = MAP/HR; if less than 1, risk present) [5] were calculated. Plasma concentrations of adrenaline and noradrenaline were assayed at TE and TE+2. Times from discontinuation of sedation to complete recovery and to tracheal extubation were noted.

Results (mean (SEM)) were compared using ANOVA, with $P < 0.05$ significant.

Groups were similar in age, weight, height, sex and temperature course of the patients, surgical procedure and total amounts of anaesthetic and postoperative drugs administered. Time between completion of surgery and initiation of sedation (2.27 (0.10) h in group P and 2.10 (0.15) h in group F), and T0 values of the studied variables were not statistically different.

Total doses were propofol 3.2 (0.3) mg kg^{-1} h^{-1} and flunitrazepam 15 (2) µg kg^{-1} h^{-1}. One patient (from group F) required one morphine injection (5 mg) at T1.

Metabolic and haemodynamic data are shown in table I. During sedation, $\dot{V}O_2$ changes were not statistically different in the two groups. The loading dose induced a 25% decrease in $\dot{V}O_2$. $\dot{V}O_2$ decreased further by 15% for the sedation period to reach its smallest value at TE. In group P, $\dot{V}O_2$ values were significantly greater at TE+0.5 than at TE and later remained unchanged. In group F, $\dot{V}O_2$ increased more slowly, with a significant difference only between TE+0.5 and TE+2. Measured $\dot{V}O_2$ values were 156%, 94% and 110% of theoretical resting $\dot{V}O_2$ values at T0, TE, and TE+2, respectively, in group P, and 168%, 111% and 120% in group F.

$\dot{V}CO_2$ did not differ between groups. The decrease in energy expenditure between T0 and TF amounted to 35%. Baseline energy expenditure was similar in the two groups (20.1 (0.9) kcal kg^{-1} day^{-1} in group P and 19.4 (1.3) kcal kg^{-1} day^{-1} in group F). Compared with baseline values, measured energy expenditure was 181 (14)% at T0, 110 (7%) at TE, 125 (7)% at TE+0.5 and 127 (7)% at TE+2 in group P. Corresponding values in group F (176 (11)%, 118 (6)%, 112 (6)% and 125 (8)%) were not significantly different.

All patients received 5% glucose which provided a 400–450 kcal day^{-1} energy supply; an additional 200–500 kcal were provided to group P patients, because of the propofol emulsion formulation. Compared with values at T0 (0.76 in group P; 0.73 in group F), RQ was significantly greater at T6 in group P (0.82) than in group F (0.70). Values later remained slightly but not significantly greater in group P (0.82–0.85) than in group F (0.70–0.79).

After the loading dose of propofol or flunitrazepam, heart rate did not change while systolic arterial pressure decreased significantly. During maintenance infusion, haemodynamics remained unchanged. Arterial pressures did not increase after sedation was discontinued. A significant decrease in RPP was noted in group P from T0.5 to TE+2. During sedation, RPP remained greater than 12000 in four group F and three group P patients. RPP did not change after discontinuation of sedation. Seven group P patients exhibited a decrease in BI after the loading dose, as a result of the decrease in mean arterial presure; the BI of two, close to 1 at T0, decreased transiently, to 0.64 and 0.43. In this group, BI later stabilized at greater than 1. In group F, BI also decreased, but remained in excess of 1.

Plasma concentrations of adrenaline at TE and TE+2 were within normal resting values (100 (50) pg ml^{-1}): 96.4 (56.4) pg ml^{-1} and 121.0 (59.9) pg ml^{-1} in group P, and 60.2 (17.5) pg ml^{-1} and 74.0 (20.8) pg ml^{-1} in group F. Plasma concentrations of noradrenaline showed a 2- or 3-fold increase from the normal range (400 (150) pg ml^{-1}): 1245.3 (453.1) pg ml^{-1} and 1273.0 (270.7) pg ml^{-1} in group P; 862.1 (129.6) pg ml^{-1} and 981.0 (184.0) pg ml^{-1} in group F at TE and TE+2, respectively. These values did not differ between the two groups.

Weaning after stopping sedation was achieved within 15 (2) min and 264 (108) min in groups P and F, respectively ($P < 0.001$). The time from discontinuation of sedation to tracheal extubation was dramatically shorter in group P (30 (3) min) than in group F (468 (153) min).

COMMENT

Because propofol has a rapid onset of action, rapid metabolism, and does not cumulate, continuous infusion has become popular for sedation of patients in the ICU [1–3]. The dose given in this study

(3.2 (0.3) mg kg^{-1} h^{-1}) was close to that used by Beller to maintain a value of 4 on Ramsay's scale in critically ill patients [3]. We compared propofol with flunitrazepam because flunitrazepam is the agent usually given in our ICU. Flunitrazepam has a rapid onset of action, but oversedation leading to delayed weaning from mechanical ventilation is a frequent side effect, as observed in our study.

Large plasma concentrations of noradrenaline were observed in both groups at the end of the period of sedation. Such increases are usual after major surgery as a part of the reaction to stress. As the stress response is not suppressed totally by opioids in usual clinical doses, it cannot be related to visceral pain only [6].

Indirect calorimetry provided immediate direct evidence of the metabolic benefits of sedation: both regimens decreased $\dot{V}O_2$ and energy expenditure by 25%: both variables were previously 1.6 to 1.7 times greater than predicted resting values. As hypnotics alter haemodynamic state, simultaneous measurement of oxygen delivery would have been necessary to assess any benefit of the decrease in $\dot{V}O_2$. At TE+1 and TE+2, $\dot{V}O_2$ remained close to T+0.5 values in the two groups. These results differ from those of Dumont and colleagues [1], who reported a brisk increase in $\dot{V}O_2$ to the postoperative presedation value soon after discontinuation of propofol. However, Dumont and colleagues' procedure was based on a shorter sedation time than ours and $\dot{V}O_2$ was measured over a 5-min period only, 5 min after the infusion was stopped.

RQ variations were not important. However, values in group P were transiently significantly greater, suggesting storage of fat from the propofol emulsion.

During postoperative sedation, infusion rates of hypnotic agents must be adjusted to avoid both oversedation and awakening. Our data suggest that bedside indirect calorimetry might be useful to decide when initiation of sedation is appropriate and to monitor it. Waiting for total recovery from general anaesthesia before initiating sedation allows full assessment of the patient, but it may be deleterious from a metabolic point of view and requires an initial loading dose, which may be risky in some patients.

HEPATIC ELIMINATION OF DIAZEPAM: INTERACTIONS WITH ALBUMIN, DESFLURANE AND SEVOFLURANE

O. DALE, E. J. FRINK, L. THOMMESEN AND A. J. GANDOLFI

SUMMARY

We have studied the effect of sevoflurane and desflurane on the hepatic elimination of diazepam, by incubating slices of rat livers in a closed system. Protein free and protein containing (albumin 10 g litre^{-1}) buffers were used to examine the effect of the anaesthetics on enzyme activity and diazepam binding to albumin. Both anaesthetics (in concentrations of 0.5, 1.5 and 3.0 mmol litre^{-1}) reduced the elimination of diazepam slightly in the absence of albumin, while the presence of the protein increased elimination to a maximum of 30% at the greatest concentration of the anaesthetics. These data support previous observations that volatile anaesthetics may interact pharmacokinetically with both liver enzyme activity and drug binding to albumin. (Br. J. Anaesth. 1993; **70**: 454–455)

KEY WORDS

Anaesthetics, volatile: desflurane, isoflurane. Biotransformation: diazepam, enzyme activity. Interactions.

It has been reported previously that volatile anaesthetics and albumin may interact *in vitro* with the elimination of diazepam in rat liver by interference with both enzyme activity and drug–protein binding [1]. Apparently, enflurane increased the rate of diazepam elimination in the presence of albumin by displacing the drug, while the elimination rate was decreased slightly in the absence of the protein [1]. In contrast, isoflurane had no effect on these processes. Halothane caused the most marked reduction in diazepam elimination in the absence of albumin, probably as a result of inhibition of hepatic drug metabolizing enzymes.

In the present study, we have examined the effects of sevoflurane and desflurane on the elimination of diazepam with and without albumin in the rat liver slice model.

METHODS AND RESULTS

Sevoflurane and desflurane were obtained from the Maruishi Pharmaceutical Co. (Osaka, Japan) and Anaquest (Madison, WI, U.S.A.), respectively. Human serum albumin (Sigma A-1653) was purchased from Sigma Chemical Co (St Louis, MO, U.S.A.). Diazepam and prazepam were obtained from Roche-Norge A/S, Oslo, Norway.

The experimental and analytical procedures have been described elsewhere [1, 2]. Briefly, livers were excised from male Sprague–Dawley rats killed by decapitation. Slices were prepared according to standard procedures and mounted on the inner wall of a stainless steel mesh cylinder. This cylinder was incubated with the buffer under constant rotation at 37 °C for 2 h in screw-capped incubation vials. The

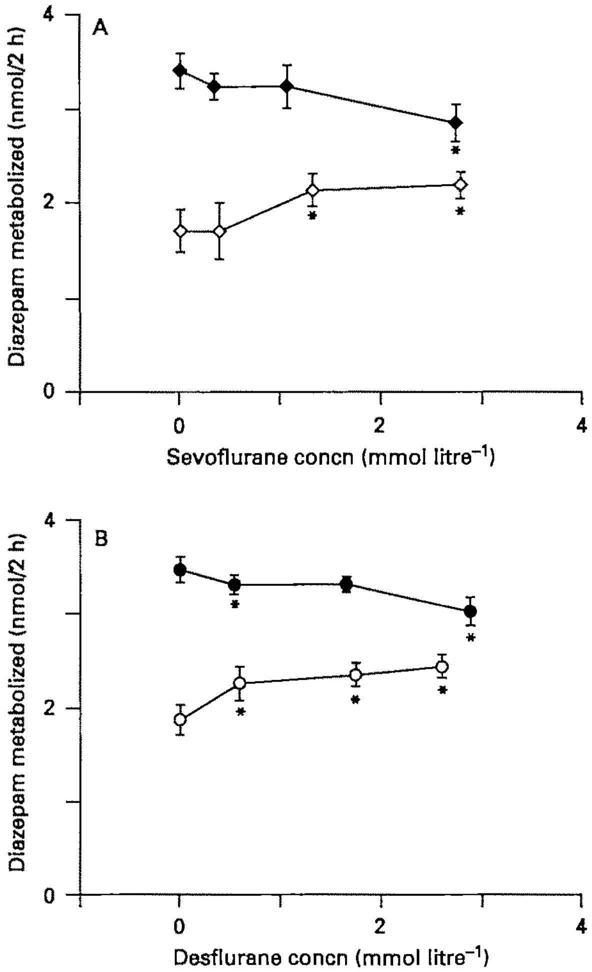

FIG. 1. Effect of sevoflurane (A) and desflurane (B) on the elimination of diazepam by rat liver slices at 37 °C for 2 h, with no albumin (filled symbols), or with albumin 10 g litre^{-1} (open symbols). Each point (mean, SD) represents 10 vials from five separate rat livers. *Statistically different from control ($P < 0.05$).

OLA DALE, M.D., PH.D.; LIV THOMMESEN, B.SC.; University of Trondheim, Department of Pharmacology and Toxicology, University Clinic, 7005 Trondheim, Norway. EDWARD J. FRINK JR., M.D.; A. JAY GANDOLFI, PH.D.; University of Arizona, Department of Anesthesiology, Health Sciences Center, Tucson, AZ 85724, U.S.A. Accepted for Publication: October 9, 1992.

anaesthetics were injected through Teflon-coated screw-caps by microsyringes (Supelco Inc., Bellefonte, Pennsylvania, U.S.A.) to achieve approximate equimolar concentrations of 0.5, 1.5 and 3.0 mmol litre^{-1} in the buffer analysed as described by Ghantous and colleagues [3, 4]. Diazepam elimination was calculated from each vial by subtracting the final concentration from the initial (2.5 µmol litre^{-1}) concentration.

Results are presented as mean (SD). Groups were compared by ANOVA. $P < 0.05$ was considered significant (Fischer test) using StatView II (Abacus Inc, Berkeley, California).

In the absence of albumin, there was a small, but statistically significant concentration-dependent reduction (15 % at 3 mmol litre^{-1}) in hepatic elimination of diazepam with both anaesthetics (fig. 1).

The presence of albumin 10 mg ml^{-1} reduced hepatic elimination of diazepam by about 50 % compared with the controls. With the addition of sevoflurane, statistically significant increases in hepatic elimination of diazepam occurred with the larger concentrations (1.5 and 3 mmol litre^{-1}). Desflurane increased the elimination of diazepam at all concentrations. Both anaesthetics increased the elimination by almost 30 % with the greatest concentration.

COMMENT

We have found that both sevoflurane and desflurane reduced the hepatic elimination of diazepam in rat liver slices in the absence of albumin, probably caused by a slight inhibition of hepatic enzyme activity. The agents were far less potent than halothane in this respect, as they reduced the elimination of diazepam by 15 % in concentrations of approximately 3 mmol litre^{-1}; a similar reduction was produced by halothane 1 mmol litre^{-1} under the same experimental conditions [1].

As has been reported for enflurane [1], the most significant interaction observed was an increase in elimination of diazepam, in the presence of albumin, with both desflurane and sevoflurane. Hepatic uptake of diazepam is confined to the free fraction. The major binding protein of diazepam in serum is albumin. Its presence in the buffer therefore reduces hepatic uptake of diazepam and consequently also its elimination, as shown in this and previous studies [1, 5]. If an agent such as enflurane, capable of displacing diazepam from albumin [5] is added to the buffer, increased elimination of diazepam results [1]. It seems likely, therefore, that the increased elimination of diazepam caused by the agents in the presence of albumin, particularly by desflurane, may be explained by an anaesthetic-induced increased free fraction of diazepam. It is worth noting that the real increase in elimination caused by diazepam displacement is not merely 30 %, but approximately 45 %, because of the 15 % reduction in enzyme activity that occurred in the absence of albumin.

What is the clinical relevance of our findings? Clinical anaesthesia with sevoflurane results in serum concentrations of about 0.5–0.7 mmol litre^{-1} [6], which is close to the smallest concentrations used here. When desflurane is used for clinical anaesthesia, the blood concentrations are thought to be in the same range as those for sevoflurane [7]. It seems unlikely, therefore, on the basis of our data, that sevoflurane may undergo any clinically relevant pharmacokinetic interactions with diazepam, but this cannot be ruled out for desflurane.

ANAESTHETIC PROPERTIES OF DIMETHYLTHIOUREA†

D. D. KOBLIN, M. J. LASTER AND J. LIU

SUMMARY

We have examined dimethylthiourea, a potent scavenger of free radicals, for its anaesthetic properties in mice and rats. In mice, dimethylthiourea abolished the righting reflex at intraperitoneal doses greater than 1.5 mg g^{-1} bodyweight; in rats, it decreased the MAC value for isoflurane in a dose-dependent fashion. Dimethylthiourea 0.5 g kg^{-1} decreased isoflurane MAC by 23%; at a dose of 2.0–4.0 g kg^{-1}, it abolished the response to tail clamp. Doses of 4.0 g kg^{-1} were lethal in the presence of isoflurane. A serum concentration of dimethylthiourea approximately 1 mg ml^{-1} produced a 50% reduction in isoflurane MAC. These anaesthetic properties of dimethylthiourea may influence experimental studies that examine the biochemical and physiological properties of this agent. (Br. J. Anaesth. 1993; **70**: 456–458)

KEY WORDS

Anaesthetics, volatile: isoflurane. Pharmacology: dimethylthiourea. Potency, anaesthetic: ED_{50}.

1,3-Dimethylthiourea [$CH_3NHCSNHCH_3$] is a scavenger of hydroxyl radicals [1]. Its administration to animals reduces the cellular injury associated with the production of hydroxyl radicals in several tissues. For example, dimethylthiourea prevents granulocyte-mediated oxidant lung injury [1], reduces brain oedema and infarct size after middle cerebral artery occlusion [2], decreases hyperoxia-induced injury [3] and reduces myocardial infarct size after occlusion of the left anterior descending coronary artery [4].

We have found in earlier studies that dimethylthiourea given to mice impeded inactivation of the enzyme methionine synthase by nitrous oxide [5]. These experiments also revealed that this scavenger had a sedative effect that increased with increasing dose. In the present study, we have assessed the anaesthetic properties of dimethylthiourea, by measuring its ability to abolish the righting reflex in mice and to decrease the requirement for isoflurane in rats.

METHODS AND RESULTS

These investigations were approved by the Animal Studies Subcommittee at the Veterans Administration Medical Center. Adult male ICR mice (29–35 g) and adult male Sprague–Dawley rats (330–430 g) were studied.

Mice were given intraperitoneal (i.p.) injections of dimethylthiourea 1.25, 1.50, 1.75, and 2.0 mg/g body weight. The time between injection and loss of righting reflex was defined as the sleep onset time. Mice were considered to have lost their righting reflex if, when placed in a supine position, they did not completely right themselves three times within 60 s. The time between the loss and recovery of the righting reflex was defined as the sleep time. After awakening (recovery of righting reflex), mice were killed with 100% carbon dioxide and blood was removed from the inferior vena cava for analysis of dimethylthiourea. Values at each dose were derived from four to eight mice.

In order to assess the effect of dimethylthiourea on isoflurane MAC, rats were placed into individual Perspex cylinders, administered 2.5–3.0% atm isoflurane for 10 min, and removed transiently from the cylinders for i.p. injections of dimethylthiourea 0 (saline control), 0.5, 1.0, 2.0 or 4.0 g kg^{-1}. Six rats were examined for each dose. Each rat received the same volume of i.p. solution (2 ml/100 g body weight). Rats were returned to the cylinders, given approximately 1.6% isoflurane in oxygen for 1 h, and examined for purposeful movement in response to a tail clamp applied for 1 min. The first concentration of isoflurane tested prevented movement to the tail clamp stimulus in all rats. Isoflurane concentration was then decreased by approximately 20%, allowed to equilibrate for at least 15 min, and the tail clamp stimulus repeated. If movement occurred, the animal was killed with 100% carbon dioxide and blood was removed from the inferior vena cava for analysis of dimethylthiourea. If no movement occurred, the isoflurane concentration was again decreased and the rat was retested to the tail clamp stimulus after equilibration of isoflurane. MAC was calculated as the mean of the isoflurane concentrations that just permitted and prevented movement.

Observations were made by an individual who was blind to the dose of dimethylthiourea injected. Isoflurane was measured by infra-red analysis.

†A preliminary report of part of these results was published in *Anesthesiology* 1988; **69**: A616.

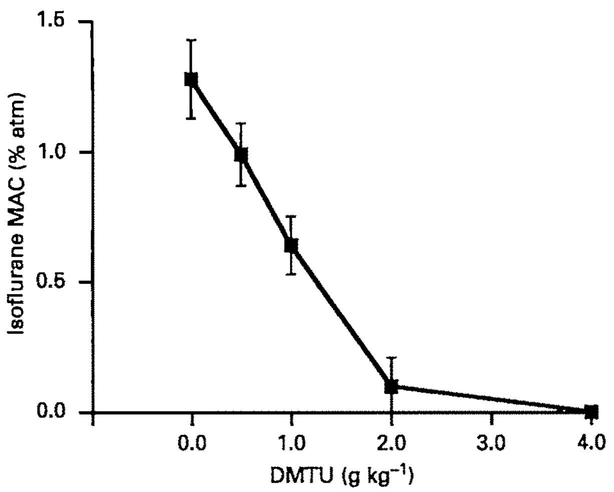

FIG. 1. Isoflurane MAC in rats given i.p. injections of dimethylthiourea (DMTU). Each point represents the results from six rats; error bars = SD. Four of six rats injected with DMTU 4.0 g kg^{-1} died during the course of the experiments.

Carbon dioxide concentrations were maintained less than 0.8% and rectal temperatures in the range 36.5–38.0 °C. Serum concentrations of dimethylthiourea were measured by gas chromatography [5]. All values are given as mean (SD).

At doses greater than 1.5 mg g^{-1}, dimethylthiourea consistently abolished the righting reflex in the mouse. Immediately after injection of dimethylthiourea, no sedative effect was noticeable. Mice remained spontaneously active and developed increasing degrees of ataxia about 10 min after injection (depending on the animal and the dose). Spontaneous activity decreased gradually with time until the animals eventually lost the ability to right themselves. No excitatory effects of dimethylthiourea could be detected. Increasing doses of the drug (1.5, 1.75 and 2.0 mg g^{-1}) were associated with shorter sleep onset times (87 (36.4) min, 36 (14.9) min and 31 (9.0) min), and sleep times increased (123 (88.5) min, 250 (57.4) min and > 600 min). Dimethylthiourea 1.25 mg g^{-1} did not consistently produce loss of righting reflex. In the two of eight animals that lost their righting reflex at this smallest dose, the sleep onset times exceeded 3 h. After dimethylthiourea 2.0 mg g^{-1}, unstimulated mice did not right themselves 10 h after the injection. Serum concentrations of dimethylthiourea at the time mice regained the righting reflex varied in the range 2.7–3.2 mg ml^{-1}.

Dimethylthiourea enhanced the potency of isoflurane in rats. Isoflurane MAC decreased from 1.28 (0.15) % in animals given i.p. injections of saline to 0.99 (0.12) % in rats injected with dimethylthiourea 0.5 g kg^{-1} ($P < 0.05$). Larger doses progressively decreased the requirement for isoflurane (fig. 1), with rats given 2 g kg^{-1} having an isoflurane requirement of 0.10 (0.11) %. Four of six rats given dimethylthiourea 4.0 g kg^{-1} died 1–3 h after starting isoflurane administration. The two other rats given the 4.0-g kg^{-1} dose did not respond positively to the tail clamp stimulus 20 min after the inspired isoflurane concentration was decreased to zero. The lower isoflurane MAC with increasing i.p. doses of dimethylthiourea corresponded to an increase in concentration of the scavenger in serum. After doses of dimethylthiourea 0.5, 1.0, 2.0, or 4.0 g kg^{-1}, its serum concentrations were 0.64 (0.15), 1.06 (0.15), 2.18 (0.18) and 3.96 (1.36) mg ml^{-1}, respectively.

COMMENT

Our results demonstrate that dimethylthiourea has anaesthetic properties. It consistently abolished the righting reflex in mice at doses greater than 1.5 mg g^{-1}—a reversible effect for a narrow range of doses. In the absence of inspired isoflurane (fig. 1), dimethylthiourea 4.0 g kg^{-1} also abolished the response to a tail clamp stimulus in rats. These anaesthetic doses of dimethylthiourea exceed the doses (typically 0.5 g kg^{-1}) used to ameliorate cellular injury [1–4]. However, the drug appeared to have a partial anaesthetic effect even at 0.5 g kg^{-1}, as this dose produced a 23% reduction in isoflurane MAC (fig. 1).

The anaesthetic properties of dimethylthiourea mimic those of a barbiturate. For example, as with dimethylthiourea, less thiopentone is needed to abolish the righting reflex than to prevent response to a stimulus to the tail. In common with dimethylthiourea, thiopentone reduces MAC for an inhaled agent in a dose-dependent fashion [6]. However, dimethylthiourea is approximately two orders of magnitude less potent than thiopentone as an anaesthetic. A 50% reduction in halothane MAC is produced at a thiopentone plasma concentration of 7.4 μg ml^{-1} [6], whereas a 50% reduction in isoflurane MAC was produced at a serum concentration of dimethylthiourea about 1 mg ml^{-1}. Thus, the anaesthetic properties of the latter (large doses and large serum concentrations required for anaesthesia; long sleep onset times after i.p. injection) are more similar to those of a barbiturate of low potency, such as barbitone, than to those of a barbiturate of high potency, such as thiopentone.

The finding that dimethylthiourea has anaesthetic properties has experimental implications. In studies that demonstrate a protective effect of dimethylthiourea (presumably related to scavenging of free radicals), appropriate controls need to be performed to show that the effect observed is a direct pharmacological action of the drug, rather than the effects of anaesthesia *per se* on the system.

CASE REPORTS

SPONTANEOUS EXCITATORY MOVEMENTS DURING RECOVERY FROM PROPOFOL ANAESTHESIA IN AN INFANT: EEG EVALUATION

A. BORGEAT, O. H. G. WILDER-SMITH, P. A. DESPLAND AND P. RAVUSSIN

SUMMARY

Spontaneous excitatory movements have been observed during recovery from propofol anaesthesia in children. Epilepsy has been postulated as a possible mechanism to explain these movements. We report the first case in which these spontaneous excitatory movements were studied using simultaneous multichannel EEG recordings. (Br. J. Anaesth. 1993; **70**: 459–461)

KEY WORDS

Anaesthetic techniques: intravenous. Anaesthetics intravenous: propofol. Complications: spontaneous excitatory movements.

Spontaneous excitatory movements have been observed during both induction and recovery from propofol anaesthesia [1–3]. Although there have been several case reports of "seizures" or opisthotonus during recovery from propofol anaesthesia [4–7] none of these has been evaluated by simultaneous EEG recordings.

An infant had exhibited spontaneous excitatory movements during recovery from previous propofol anaesthetics. In the course of a subsequent propofol anaesthetic, we were able to study these spontaneous excitatory movements using simultaneous multichannel EEG recordings.

CASE REPORT

The patient was a 6-week-old, otherwise healthy, 4-kg young girl. She was admitted for radiotherapy (35 courses of 3 min duration) of her congenital bilateral retinoblastoma. During the first two treatments, anaesthesia was performed with propofol. In the course of each recovery, spontaneous excitatory movements (graded stage 3 according to the previously described classification [3]) were observed, lasting 15–20 min until full awakening. The anaesthetic technique used was as follows: premedication with oral atropine 0.15 mg; local anaesthesia for venous cannulation (24-gauge) insertion using EMLA cream on the back of both hands. In the anaesthesia room, heart rate, arterial pressure and Sp_{O_2} were recorded. Anaesthesia was induced with a bolus of propofol 20 mg i.v. The lungs were ventilated manually with oxygen (FI_{O_2} 100 %). For the third course of radiotherapy, we decided to record the multichannel EEG during the phase of excitatory movements. After induction of anaesthesia (as described above) and completion of radiotherapy treatment, the child received a supplementary bolus of propofol 5 mg i.v. to facilitate placement of the EEG electrodes. Twelve intradermal needle electrodes were placed according to the 10–20 international system.

Electrode impedances were less than 6 kΩ. A CEM EEG recording machine (Vickers, U.K.) was used to record eight channels. The high frequency filter was set at 70 Hz; bipolar longitudinal montages were used. An ECG was recorded simultaneously on one channel.

Four minutes after the last bolus of propofol, the EEG recordings analysed by our specialist electroencephalographer, showed fast waves (10 Hz) with a mean voltage 50 µV coupled with theta waves (voltage 100–200 µV) (fig. 1). No spontaneous movements were noted. As the infant started to awake, excitatory movements involving the four limbs and the trunk appeared 7 min after the last dose of propofol. These movements were choreiform with extension, flexion and intermittent jerking of the limbs. They lasted up to 20 min until full awakening. The EEG recording during this period (7 min after last bolus of propofol) was characterized by blocking alpha-waves associated with symmetrical delta–theta waves (voltage 50–100 µV) (fig. 2). Spikes, spike-waves or other epileptogenic patterns were not observed. During the whole procedure, heart rate, arterial pressure and Sp_{O_2} (98–99 %) remained stable. The postoperative course was otherwise uneventful. The next day, an awake and asleep EEG were performed. These recordings were unremarkable. The same anaesthetic procedure coupled with an EEG recording was performed during the 23rd course of treatment. The results were similar to those reported above.

DISCUSSION

This is the first report of simultaneous continuous EEG recordings during spontaneous excitatory movements in an infant recovering from propofol anaesthesia. In this patient, the EEG recordings demonstrated deep anaesthesia with no signs of

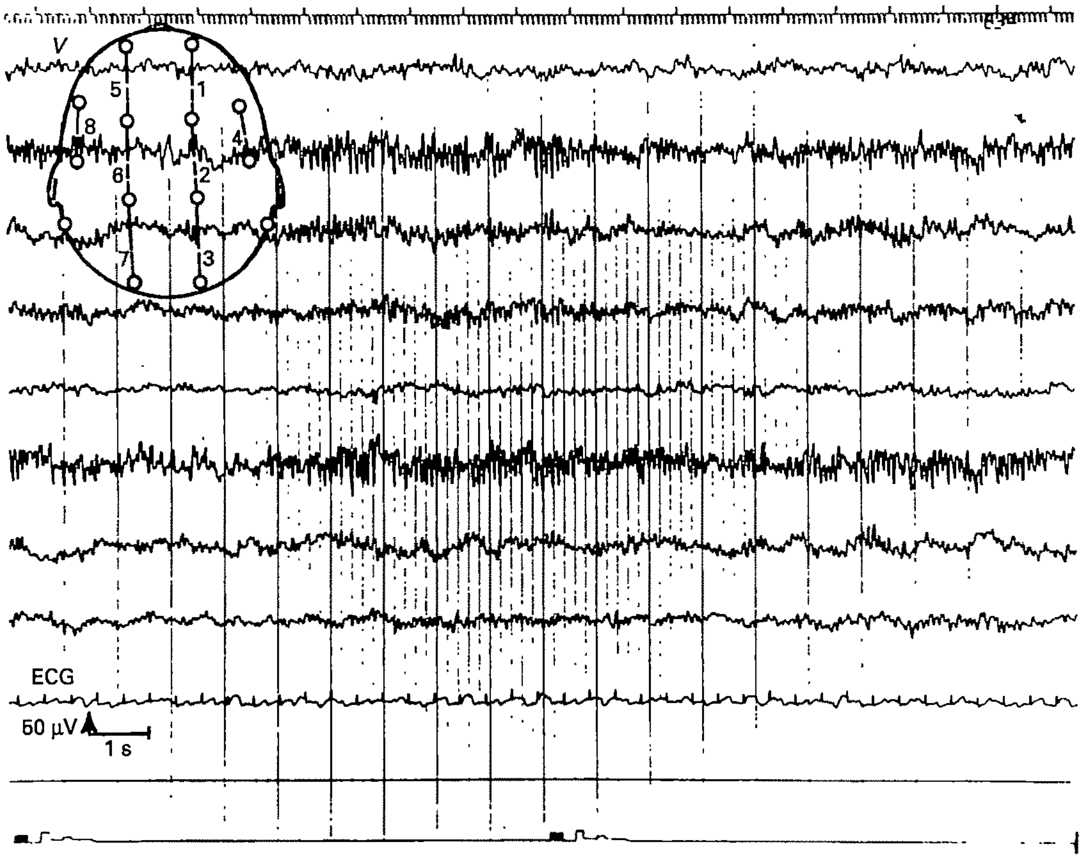

FIG. 1. EEG after induction demonstrating beta and theta activities: no spontaneous excitatory movements.

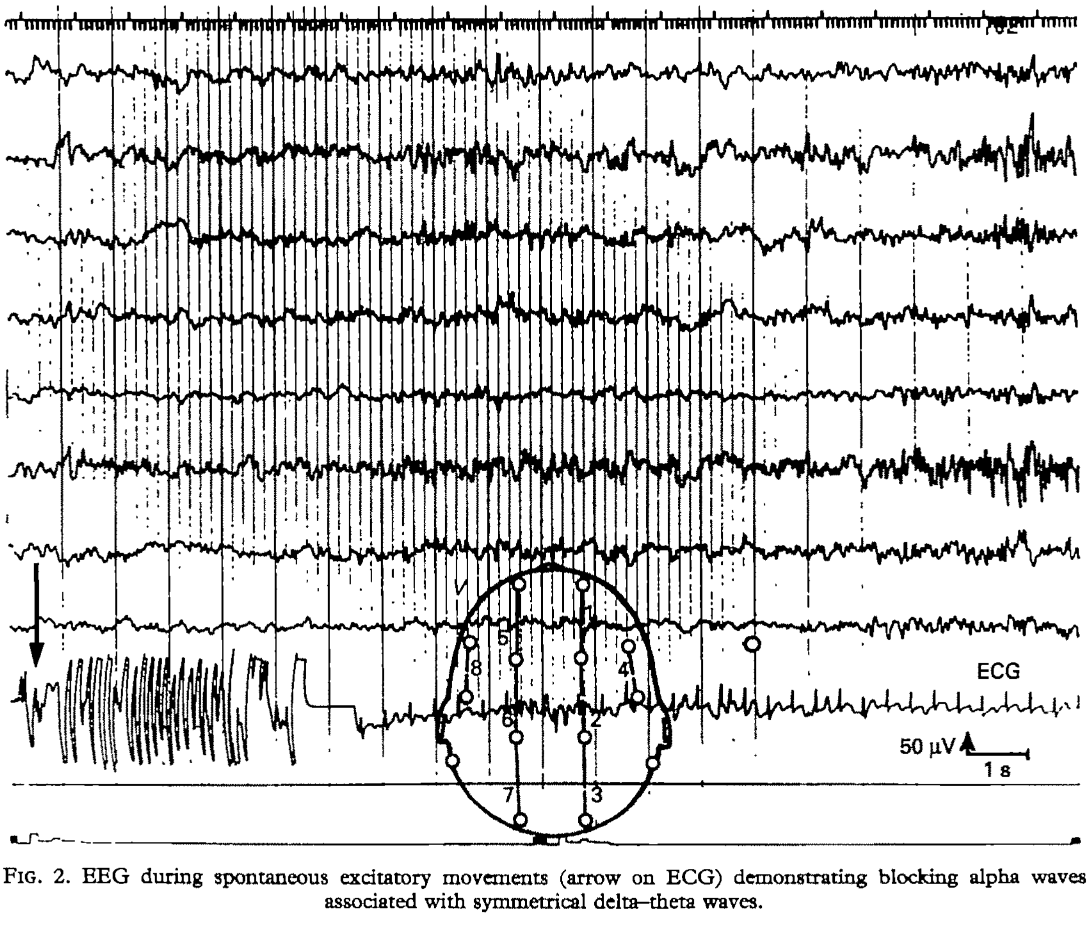

FIG. 2. EEG during spontaneous excitatory movements (arrow on ECG) demonstrating blocking alpha waves associated with symmetrical delta–theta waves.

epileptiform activity. Although there have been several case reports of "seizures" or opisthotonus during recovery from propofol anaesthesia that might have implicated propofol as a convulsant [4–7], careful studies conducted in both animals and humans strongly suggest that, on the contrary, propofol possesses anticonvulsant properties [8–10].

Spontaneous movements occur during induction and recovery from propofol anaesthesia; they have been observed in adults [1, 2] and in children, with a greater incidence in the latter group [3], suggesting an age-dependent differential sensitivity of this phenomenon. We demonstrated recently that, in children, larger induction doses of propofol are associated with a decreasing incidence of spontaneous movements [3]. This child received a large induction dose (5 mg kg^{-1} i.v.—usual dose, 3–4 mg kg^{-1}), thus explaining the lack of spontaneous excitatory movements during the induction phase.

The origin of these movements remains unknown. However, recent evidence suggests involvement of subcortical structures. Indeed, recent studies have demonstrated that subhypnotic doses of propofol possess antiemetic and antipruritic properties [11, 12], which tend to lend support to other subcortical actions of propofol. Interestingly, in these studies the duration of action of propofol was much longer than the hypnotic or cortical durations of action of much greater doses of propofol. This would suggest a much greater sensitivity to propofol of non-cortical structures, compared with cortical areas.

Recently, Kalkman and colleagues showed that propofol 2 mg kg^{-1} i.v. caused significant depression of both electrical and magnetic transcranial motor evoked responses which significantly outlasted any anaesthetic or sedative effects [13]. This marked disparity between the subcortical electrophysiological effects and the apparent (cortical) effects on consciousness is also consistent with significant disparities between the cortical and subcortical pharmacodynamics of propofol. In a study investigating the basic mechanisms associated with excitatory movements caused by propofol anaesthesia, Dolin and colleagues found that excitatory behaviour observed in mice receiving intraperitoneal propofol were augmented by strychnine, a glycine antagonist [14]. Glycine is a ubiquitous amino acid in the central nervous system; however, in its role as an inhibitory neurotransmitter it appears to be confined to subcortical areas [15].

In conclusion, this case report confirms that the spontaneous excitatory movements observed during recovery from anaesthesia with propofol are not associated with cortical epileptic activity and do not differ (nature and origin) from those observed during induction. Although the possibility of true non-cortical seizure activity cannot be excluded, the evidence increasingly points towards other subcortical mechanisms.

A CONTINUOUS SUBDURAL BLOCK

C. B. COLLIER, S. P. GATT AND S. M. LOCKLEY

SUMMARY

We describe a case of accidental subdural block, after attempted extradural puncture for Caesarean section. Fractionation of the local anaesthetic dose led to avoidance of more serious complications. Subdural fentanyl and a continuous low-dose subdural infusion were used satisfactorily for intra-operative management and postoperative analgesia. As little as 0.5 ml of bupivacaine, hourly, provided satisfactory analgesia over a 15-h period. (Br. J. Anaesth. 1993; **70**: 462–465)

KEY WORDS

Anaesthesia: obstetric. Anaesthetic techniques: extradural, subdural.

Subdural (extra-arachnoid) blocks have been used in the treatment of intractable pain for many years, since the pioneering work by Maher in 1957 [1]. However, the first well-illustrated description of an accidental subdural block, leading to collapse of the patient in the course of a planned extradural block, was that of Boys and Norman in 1975 [2]. Several reports have followed, usually of obstetric patients [3, 4].

There have been few communications on the effects of subdural opioids [5, 6] and none describing satisfactory continuous subdural local anaesthetic block.

CASE REPORT

A 31-yr-old Samoan lady (height 165 cm, weight 77 kg) presented in early labour at 38 weeks gestation, with spontaneous rupture of membranes and an oblique lie. An urgent Caesarean section was planned. The patient had received uneventful extradural blocks for three of her four previous vaginal deliveries and she requested to be awake on this occasion.

18:20. After i.v. infusion of Hartmann's solution 1 litre, the patient was placed in the left lateral position. The extradural space was located easily at the L2–3 level, in the midline, using a 16-gauge Tuohy needle and loss of resistance to air. After negative aspiration for blood or CSF, a dose of 2% lignocaine 4 ml with adrenaline was given through the needle.

18:40. Because of unforeseen circumstances, it was 10 min after the first injection when a test dose of 2% lignocaine 4 ml with adrenaline and fentanyl 40 μg was given through the catheter (after negative aspiration).

18:45. Testing of sensation to pinprick now revealed sensory block to T2. Systolic arterial pressure (SAP) decreased to 70 mm Hg and ephedrine 15 mg was given i.v. over 20 min. This, together with a second 1 litre of Hartmann's Solution restored SAP to 100 mm Hg.

The patient was neither distressed nor drowsy and had no pupillary changes or ventilatory difficulty. Dense motor block in the lower limbs developed over the next few minutes. Fetal cardiotocographic monitoring showed a normal pattern.

19:00. When SAP and sensory level were fairly stable, surgery was commenced.

19:27. A healthy infant was delivered with Apgar scores of 10 and 10, at 1 min and 5 min. The patient had no discomfort during delivery, but at 19:40 she complained of lower abdominal pain during peritoneal closure. This responded to pethidine 20 mg i.v. Attempted aspiration of CSF through the extradural catheter was negative at this time and on several other occasions.

20:15. After completion of surgery (almost 2 h after the block), examination revealed no residual motor or sensory loss and the presence of only mild abdominal discomfort.

20:30. The patient was transferred to the Obstetric Acute Care Unit and an infusion of 0.1% bupivacaine plain was set to run through the "extradural" catheter at 1 ml h^{-1}. Within 1 h, good analgesia was obtained, with sensory block to T12 and minimal motor block.

23:00. The patient remained comfortable, but the sensory block had now risen to T2 and the infusion was stopped. SAP was stable at 100 mm Hg.

02:00. Early the following morning, the patient awoke complaining of pain. The sensory block had regressed to T12. A 1-ml bolus of 0.1% bupivacaine was given, resulting in 2 h of analgesia and sensory block to T4.

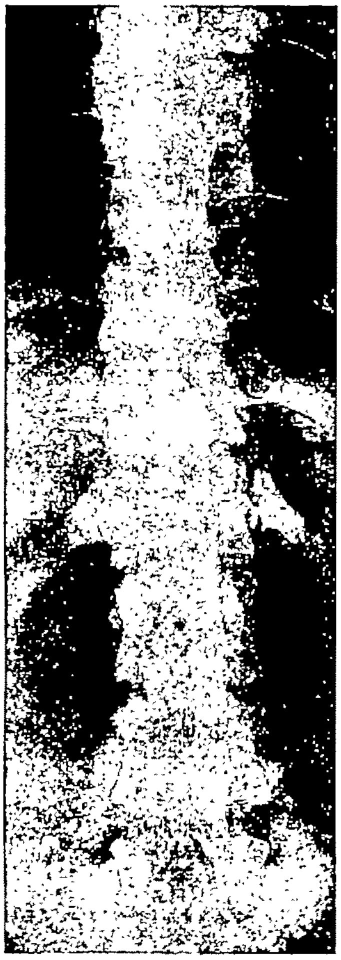

FIG. 1. Antero-posterior radiograph of thoracolumbar spine, showing subdural spread of contrast.

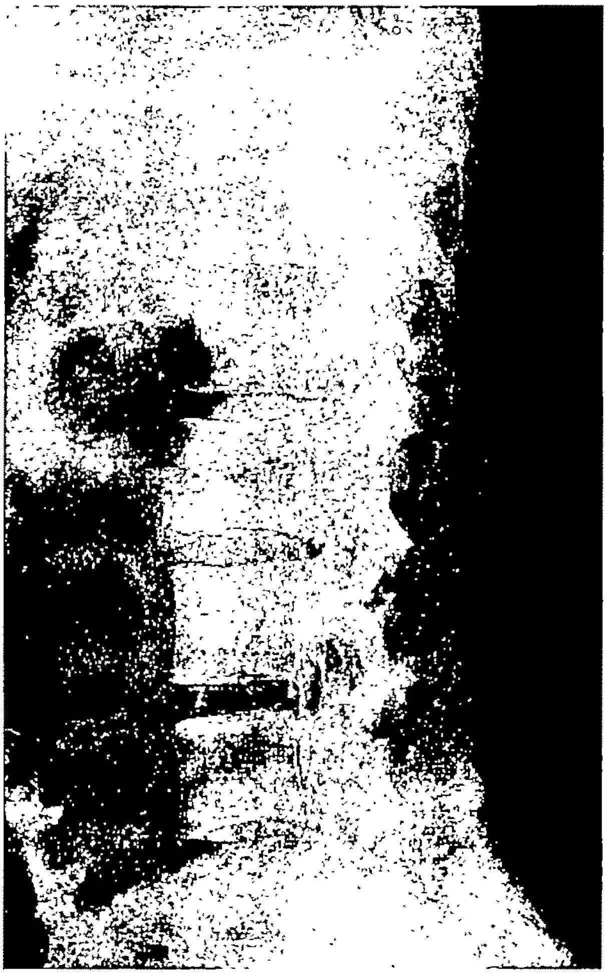

FIG. 2. Lateral radiograph of spine, showing marked ventral and dorsal columns of contrast.

04:00. Three additional boluses of 0.5 ml were given hourly to maintain analgesia. The patient slept well, but was always easily rousable, with only slight heaviness of the legs. As 0.5 ml h^{-1} appeared to be a satisfactory dose, the infusion was restarted at this rate, with good analgesia ensuing.

12:00. The infusion was ceased, a total of 9 ml of bupivacaine having been administered over 15 h. The patient consented to contrast injection and x-ray screening as part of our continuing study of atypical extradural blocks, which are investigated radiographically, after Hospital Ethics Committee approval. In this patient we wished to determine the site of catheter placement, for the clinical pattern could possibly have represented either a pure subdural or subarachnoid block, or a multicompartment block, with the catheter eyes laying in different spaces [7].

Iohexol 240 10 ml was injected and the typical appearances of subdural spread of dye were observed. The antero-posterior view (fig. 1) showed the characteristic "rail-road tracks", from T4 to L4, whilst the lateral view (fig. 2) demonstrated the marked anterior and posterior columns of dye in the subdural space, with "empty" intervertebral foramina. The catheter tip was situated behind the body of the L2 vertebra.

The catheter was withdrawn and inspected, revealing no macroscopic abnormality, and then subjected to the routine testing that we have been performing on all used catheters. First, water was injected down the catheter with observation of the three resulting jets; then the catheter tip was held under water whilst air was injected into the catheter and the streams of bubbles noted. All three eyes were found to be patent, but preferential flow was directed through the proximal eye in both tests. Considerable pressure was required to produce any flow through the middle and distal eyes. Examination with a microscope at 12.5-times magnification revealed a normal proximal eye, but smaller middle and distal eyes, each of approximately 50 % the diameter of the proximal eye.

One hour after the bupivacaine infusion was stopped, sensation had returned to normal, but there was weakness of hip flexion, which resolved 4 h later. The patient made a smooth postoperative recovery, without headache or neurological problems.

DISCUSSION

The cause of this patient's hypotension and high sensory block after an apparently simple extradural block was considered initially to be either subarachnoid or subdural injection. The two conditions may be clinically indistinguishable on some occasions [3, 8]. The relatively slow onset of symptoms and the limited height of the block, together with the inability to aspirate CSF were more suggestive of a subdural block in this patient and radiological screening confirmed the diagnosis.

It appears most likely that this patient's subdural block, which developed 15 min after the 4-ml flushing dose of lignocaine was caused by this initial dose and then compounded by the test dose through the catheter, so that the clinical picture resulted from a total of 8 ml of subdural lignocaine with fentanyl, over a 10-min period. Our usual practice is to give another 6 ml 5 min after the test dose, in the absence of untoward spread, and a further dose a few minutes later, if required, thus "fractionating" the total dose.

If an unwelcome phone-call had not delayed proceedings by 10 min, the 8-ml volume would have been given over a 2–3 min period, followed 5 min later by a bolus of 6 ml. The resulting 14 ml total would almost certainly have produced a high subdural block, perhaps with apnoea and unconsciousness [3]. If "fractionation" had not been used, a bolus of 10–12 ml would have been given, probably producing even more severe symptoms.

Because of the delayed onset of subdural blocks, routine test doses are of only limited value, as it is impractical to wait 15–20 min to exclude this rare complication. However, it may be preferable to use saline for any dose given through the needle, when a continuous block is planned, as the presence of local anaesthetic before catheter insertion usually gives little useful information, except in the case of intravascular injection, and may, indeed, complicate the findings of a subsequent test dose given through the catheter, as happened here.

It is possible that the Tuohy needle was correctly positioned in the extradural space and the catheter perforated the dura on introduction, but as symptoms were noted only 5 min after the first dose through the catheter, it would be highly unlikely that this dose could have initiated the subdural block; more probably, it simply added to the volume already in the subdural space.

The x-ray findings excluded the possibility of a multicompartment block, as did the examination of the catheter after withdrawal, which suggested that only one of the three eyes of the catheter was functioning *in situ*. When the patient's condition had settled after the crystalloid solution and vasopressor agent, and in the presence of good sensory block, it seemed prudent to allow Caesarean section to commence. Other workers have resorted to general anaesthesia [9] or insertion of a second extradural catheter [10] in this situation. Our decision was influenced by the work of Germann, Roberts and Prys-Roberts [11], who demonstrated possible cardiovascular depression produced on combining general anaesthesia with a pre-existing stabilized extradural block. In our situation, the origin of the block was unknown and its stability uncertain; also it has been brought to our attention that several recent cases of maternal mortality and morbidity have involved a combination of general anaesthesia and regional block.

The pattern of the initial subdural block was fairly typical of that after a small dose of local anaesthetic, in that breakthrough pain occurred after 1 h and sensory regression was complete in less than 2 h [3].

The unintentional use of subdural opioids was first documented by Miller, Choi and Chestnut in 1989 [5], when they injected morphine 1 mg into a subdural catheter. This dose produced a 22-h duration of analgesia, with the only side effect being immediate facial flushing which subsided over 10 min. Brown, Atkinson and Standiford, also in 1989 [6], accidentally implanted an extradural catheter in the subdural space of a patient with intractable malignant pain. The catheter was used satisfactorily for morphine administration over a 3-month period, until the patient's demise, at which time he was receiving 12 mg per day.

The use of subdural fentanyl does not appear to have been reported before. A single bolus of 40 µg combined with lignocaine produced only about 1–2 h of analgesia, but there were no obvious side effects.

As many of our postoperative patients receive extradural infusions for analgesia, we continued to use the (presumed) subdural catheter in this patient over a 15-h period, with careful monitoring. A satisfactory dose, producing a fairly constant level of sensory block, with minimal motor block, was found by trial and error to be 0.1% bupivacaine 0.5 ml h^{-1}—less than 10% of our usual extradural dose, and similar to a subarachnoid dose. There appears to be only one previous description of a continuous subdural local anaesthetic infusion [12], and this patient displayed only intermittent sensory block, which may have been partially subarachnoid in origin.

We have demonstrated that it is possible to maintain satisfactory analgesia, safely, with very small doses of local anaesthetic infused into the subdural space. Deliberate subdural block may be a safer technique than continuous subarachnoid block, with its history of neurological problems [13]. However, a recent paper has suggested that neurological damage might result from compression of the spinal cord or nerve roots by a subdural catheter or the injected subdural solution [14], although there appears to be little evidence for this.

POSSIBLE VENOUS AIR EMBOLISM WITH A NEW WATER JET DISSECTOR

J. A. S. SMITH

SUMMARY

An incident of apparent major venous air embolism occurred during hepatic resection using a water jet dissector, an instrument using a high pressure, high velocity jet to disintegrate liver parenchyma. (Br. J. Anaesth. 1993; **70**: 466–467)

KEY WORDS

Complications: venous air embolism. Equipment: water jet dissector. Surgery: hepatic.

CASE REPORT

A 25-yr-old, 59-kg woman presented for left hepatic lobectomy for removal of a single nodule of benign hyperplasia.

General anaesthesia was induced with fentanyl and propofol and muscle relaxation produced with a mixture of pancuronium and vecuronium. Anaesthesia was maintained with nitrous oxide, oxygen and isoflurane at an end-tidal carbon dioxide partial pressure (PE'_{CO_2}) of 4 kPa. The patient was supine with approximately 30° head-up tilt and a sternal retractor was used to provide good exposure for the hepatic resection.

Arterial pressure was monitored invasively from the left radial artery and displayed with ECG, oxygen saturation (Sp_{O_2}) and respired carbon dioxide on a Datex Cardiocap II CG–2GS multifunction monitor coupled to a Sony Model UP-701 videographic printer. Two 16-gauge peripheral venous cannulae were inserted, but in view of the patient's youth and excellent general health a central venous catheter was considered unnecessary.

Progress was uneventful for 80 min, when PE'_{CO_2} decreased by 50% over 3 min while showing an erratic wave pattern suggesting ventilatory effort. Neuromuscular block had been allowed to wane, but the overall depth of anaesthesia and the lack of any extraordinary surgical insult made this change puzzling; nevertheless, further increments of fentanyl and neuromuscular blocker were given. However, before any effect could be expected an abrupt reduction in Sp_{O_2} occurred and the suspicion of venous air embolism raised. The surgeons readily acknowledged this possibility, as their operative field had just filled with froth and bubbles after application of a new water jet dissector. One minute later, both heart rate and arterial pressure decreased markedly, supporting the clinical diagnosis of venous air embolism. There was no change in the ECG trace other than sinus bradycardia.

Nitrous oxide was immediately discontinued and the head-up tilt reversed to increase preload and mitigate against any potential cerebral arterial gas embolism in the event of a patent foramen ovale. These measures halted the downward trend and all variables remained within acceptable limits. Sp_{O_2} and heart rate began to recover within 1 min and PE'_{CO_2} followed soon after (fig. 1). Arterial pressure remained at 85 mm Hg systolic for 5 min but then recovered promptly with removal of a pack that may have been compressing the inferior vena cava. However, the clear change in PE'_{CO_2} before the changes in heart rate and arterial pressure makes caval compression an unlikely event.

A right atrial catheter was contemplated but not inserted, as the incident was resolving before any such action could be undertaken. A precordial Doppler was applied over the right sternal edge within 5 min of the incident, but did not yield any useful information, as cardiac function was normal by this time.

Liver resection was completed uneventfully with

J. A. S. SMITH, M.B., B.S., F.R.C.ANAES., F.A.N.Z.C.A., Department of Anaesthesia and Intensive Care, Royal Adelaide Hospital, Adelaide, South Australia 5000. Accepted for Publication: October 28, 1992.

the aid of an ultrasonic dissector. Anaesthetic emergence and recovery were uneventful and there was no detectable neurological deficit.

DISCUSSION

The water jet dissector has been developed over the past decade to disintegrate liver parenchyma while sparing the biliary ducts and vascular structures. This allows better recognition and progressive control by diathermy or ligation as appropriate.

The Hepatatom [1–4] is a recent development of this principle, comprising a compressed air pump which forces liquid via a flexible hose through a fine nozzle. The high pressure, high velocity jet stream is designed to increase in diameter with distance from the nozzle tip. It remains coherent for about 30 mm and ends as a fine spray of microdroplets at 40–80 cm, depending on the pressure settings chosen. In use, the tip is advanced from about 40 mm to the point where it cuts liver and then manipulated in a to-and-fro manner as necessary to clear parenchyma. The turbulent interface of water and air at the limits of jet coherence may explain the entry of significant air to an open vein in the resection plane. A Venturi effect within the depths of the wound is another possibility.

The manufacturer's literature indicates that the total volume of fluid used is very small, with no more than 200–300 ml used even in major dissections [1–3]. We can find no mention of venous air embolism in any of the published literature.

While this was the first use of this technique on a patient in our country, it has been used successfully in more than 100 patients in Europe [G. J. Maddern, personal communication]. As this was also the first use of this particular instrument, it is possible that it was not performing to specification, but certainly the variables set were conservative.

In a subsequent laboratory experiment using this same instrument in an aggressive manner on a pig liver, no change in $P\text{E}'_{CO_2}$ could be elicited. However, on directing the jet at biliary structures, the gall bladder was seen to distend markedly with fluid and gas—apparently water and air from the dissector in approximately equal proportions.

While the operative field in surgery such as this lies below the heart and might not ordinarily predispose to venous air embolism, the fact that a turbulent interface of water and air at high pressure is generated by this machine suggests that full monitoring for the detection and treatment of venous air embolism be routine until further human experience clarifies the risk.

ACKNOWLEDGEMENT

I thank Mr G. J. Maddern who provided full details of the development of this jet dissector and invited subsequent attempts to reproduce air embolism.

APPARATUS

FRESH GAS REQUIREMENTS OF AN ENCLOSED AFFERENT RESERVOIR BREATHING SYSTEM IN ANAESTHETIZED, SPONTANEOUSLY BREATHING ADULTS

J. R. BARRIE, P. C. W. BEATTY, I. T. CAMPBELL, G. MEAKIN AND T. E. J. HEALY

SUMMARY

Using two methods of determining the onset of rebreathing, we have determined the minimum fresh gas flow rate ($\dot{V}\mathrm{F}$) of the Ohmeda enclosed afferent reservoir breathing system (EAR) in anaesthetized, spontaneously breathing adults. Rebreathing as defined by the Kain and Nunn criteria did not occur when the $\dot{V}\mathrm{F}/\dot{V}\mathrm{E}$ ratio was greater than 0.70. A mathematical model was used to calculate the degree of rebreathing at each $\dot{V}\mathrm{F}$. From this model, rebreathing did not occur when $\dot{V}\mathrm{F}$ was 0.86 $\dot{V}\mathrm{E}$ or more and this value of $\dot{V}\mathrm{F}/\dot{V}\mathrm{E}$ is considered appropriate to eliminate rebreathing in clinical practice. (Br. J. Anaesth. 1993; **70**: 468–470)

KEY WORDS

Anaesthesia: general. Equipment: breathing system, EAR system.

The enclosed afferent breathing system (EAR), developed by Ohmeda, has been demonstrated to be an efficient breathing system for paediatric use during both controlled [1] and spontaneous ventilation [2], and during controlled ventilation in adults [3]. This study was undertaken to determine the minimum fresh gas flow required to prevent rebreathing when the EAR is used during anaesthesia with spontaneously breathing adults. Preliminary work suggests that the efficiency of the EAR is maintained during anaesthesia in relatively young, healthy adults in the supine position [4]. This study aimed to determine the minimum fresh gas requirements for this system when used in elderly patients in the lithotomy position, thus assessing the efficiency of the system under less favourable circumstances found in clinical practice.

APPARATUS

A brief description of the EAR is given below (fig. 1).

A rising bellows, with a capacity of 1500 ml, is incorporated in the inspiratory limb of the system. It is filled from the fresh gas flow and drawn upon during inspiration. A one-way valve is situated in the machine end of the expiratory limb and prevents rebreathing of gas from the expiratory limb during inspiration. Gas passes back on expiration along the inspiratory limb and fills the bellows; thereafter, it spills through the one-way expiratory valve, which has an opening pressure of 1.9 cm H_2O. The system thus functions as a Mapleson A system during spontaneous ventilation.

METHODS

District Ethics Committee approval was obtained and we studied 15 patients aged 64–80 yr, ASA I–III and undergoing elective urological surgery. The patients were not premedicated. Anaesthesia was induced with propofol up to 2.5 mg kg^{-1} and maintained with 66 % nitrous oxide and 2–3 % halothane in oxygen via a laryngeal mask airway. The concentration of halothane was adjusted to obtain adequate anaesthesia and remained constant thereafter. Heart rate, arterial pressure and arterial oxygen saturation (Sp_{O_2}) were monitored non-invasively.

The following measurements were made:

Respiratory flow was measured at the junction between the patient and the breathing system using a heated pneumotachograph (Fleish No. 2). The flow signal from the pneumotachograph was integrated electronically to obtain tidal volume ($V\mathrm{T}$) and expired minute volume ($\dot{V}\mathrm{E}$).

Respiratory gases were sampled continuously from the connector of the laryngeal mask and were analysed for carbon dioxide using an infra-red carbon dioxide analyser (Datex Normocap) to determine end-tidal carbon dioxide partial pressure ($P\mathrm{E'}_{CO_2}$). This sampling resulted in the loss of 150 ml min^{-1} from the system, which was allowed for in subsequent calculations.

All data were recorded on tape (Tandberg Instrumentation Recorder series 100) and analysed via a chart recorder (Grass).

Fresh gas flow ($\dot{V}\mathrm{F}$) was initially set at 100 ml kg^{-1} min^{-1} and the above measurements were made after a 5-min period of stabilization. $\dot{V}\mathrm{F}$ was then reduced by increments of 0.1 × minute volume. Readings were repeated after a 5-min period of

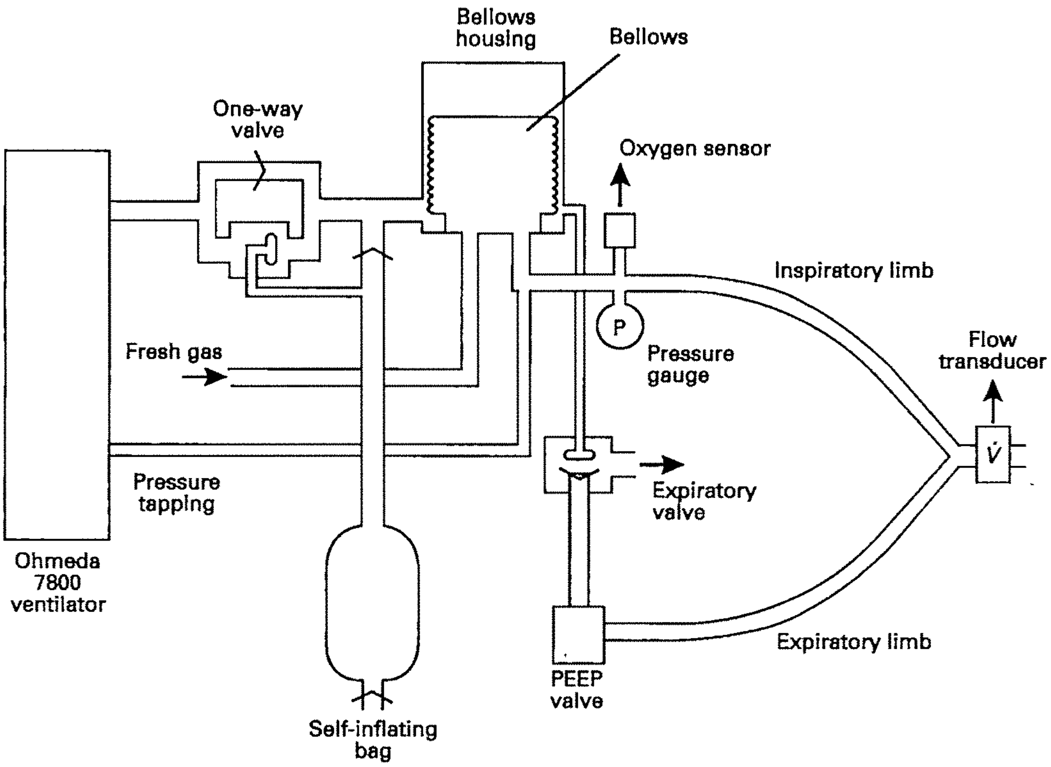

FIG. 1. Diagram of the enclosed afferent reservoir breathing system.

stabilization or when one of the following rebreathing criteria, originally outlined by Kain and Nunn [5], was met:

(i) An increase in $\dot{V}\mathrm{E}$ or tidal volume of 10% or more, not accompanied by a corresponding decrease in $P\mathrm{E}'_{\mathrm{CO_2}}$.

(ii) An increase in $P\mathrm{E}'_{\mathrm{CO_2}}$ of 0.66 kPa or more, which could not be accounted for by a decrease in $\dot{V}\mathrm{E}$.

(iii) An increase in $\dot{V}\mathrm{E}$ of 5% or more, accompanied by an increase in $P\mathrm{E}'_{\mathrm{CO_2}}$ of 0.6 kPa or more.

When the criteria for rebreathing had been met, $\dot{V}\mathrm{F}$ was increased to 100 ml kg^{-1} min^{-1}.

The mathematical model described by Meakin and colleagues [2] was then used to determine the rebreathed volume. Briefly, this assumes that, in the absence of longitudinal mixing of expired gas, rebreathing occurs when $\dot{V}\mathrm{F}$ is less than alveolar ventilation ($V\mathrm{A}$). Thus:

$$V\mathrm{R} = V\mathrm{A} - V\mathrm{F}$$

but

$$V\mathrm{A} = V\mathrm{T} - V\mathrm{D}$$

so

$$V\mathrm{R} = V\mathrm{T} - (V\mathrm{D} + V\mathrm{F})$$

where $V\mathrm{R}$ = volume of rebreathed alveolar gas per breath; $V\mathrm{A}$ = volume of expired alveolar gas per breath; $V\mathrm{F}$ = volume of fresh gas per breath; $V\mathrm{D}$ = apparatus plus anatomical deadspace.

Deadspace—apparatus plus anatomical—was determined by Fowler's method using a custom-written computer program and microcomputer. Flow and capnography signals were aligned at the point of end-expiration by associating the sudden decrease in carbon dioxide concentration with the onset of inspiratory flow [6]. $P\mathrm{E}'_{\mathrm{CO_2}}$ was then plotted against expired volume, giving a sigmoid curve. $V\mathrm{D}$ was the volume expired when the areas above and below this sigmoid portion of the curve were equal. The rebreathed volume calculated above was expressed as a percentage of the tidal volume ($V\mathrm{R}/V\mathrm{T}$%); this was plotted against $\dot{V}\mathrm{F}/\dot{V}\mathrm{E}$.

TABLE I. *Summary of results when Kain and Nunn criteria were met*

Patient no.	$\dot{V}\mathrm{F}$ (ml kg^{-1} min^{-1})	$\dot{V}\mathrm{F}/\dot{V}\mathrm{E}$	$\Delta P\mathrm{E}'_{\mathrm{CO_2}}$ (kPa)	$\Delta\dot{V}\mathrm{E}$ (%)	$V\mathrm{R}/V\mathrm{T}$%

RESULTS

Table I shows the values of $\dot{V}\mathrm{F}/\dot{V}\mathrm{E}$ and $V\mathrm{R}/V\mathrm{T}$%, together with changes in $P\mathrm{E}'_{\mathrm{CO_2}}$ and $\dot{V}\mathrm{E}$, for the values of $\dot{V}\mathrm{F}$ at which rebreathing, according to the Kain and Nunn criteria, were detected. The mean value of $\dot{V}\mathrm{F}/\dot{V}\mathrm{E}$ at which these criteria were fulfilled was 0.60, corresponding to a mean $\dot{V}\mathrm{F}$ of 62.3 ml kg^{-1}. Rebreathing according to the Kain and Nunn criteria was not seen in any patient when $\dot{V}\mathrm{F}/\dot{V}\mathrm{E}$ was > 0.7. Rebreathing was not detected in four patients.

The degree of rebreathing ($V\mathrm{R}/V\mathrm{T}$%) was related inversely to $\dot{V}\mathrm{F}/\dot{V}\mathrm{E}$ (fig. 2). Fitting an arbitrary cubic regression (by Figure Perfect; Biosoft) to the data

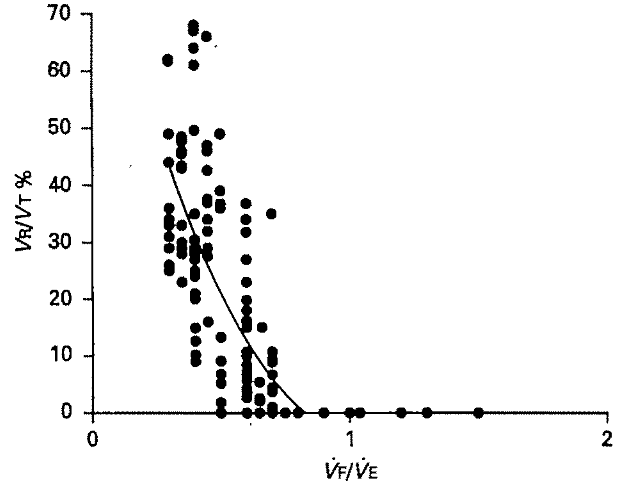

FIG. 2. Plot of the degree of rebreathing (V_R/V_T%) against the ratio of fresh gas flow to minute volume ($\dot{V}_F/\dot{V}_E$).

reveals a take-off point of $\dot{V}_F/\dot{V}_E = 0.86$, this being the value of $\dot{V}_F/\dot{V}_E$ required to eliminate rebreathing completely.

DISCUSSION

Our results indicate that the onset of rebreathing as determined by the Kain and Nunn criteria [5] occurred at mean $\dot{V}_F/\dot{V}_E$ of 0.6 and was not seen at values of $\dot{V}_F$ greater than $0.7\dot{V}_E$. Norman, Adams and Sykes reported that, with the Mapleson A system, the onset of rebreathing occurred when $\dot{V}_F/\dot{V}_E$ was 0.6–0.7 [7], whilst in Alexander's study the onset of rebreathing occurred when $\dot{V}_F/\dot{V}_E$ was 0.76 [8]. Our results are consistent with these studies.

The onset of rebreathing as determined by calculation occurs when $\dot{V}_F/\dot{V}_E$ decreases to less than 0.86. The validity of the derived onset of rebreathing depends on the validity of the assumption that there is little longitudinal mixing of expiratory gas in the delivery tube—an assumption which is fundamental to the explanation of the efficiency of the EAR and the Mapleson A system on which it is based. The $\dot{V}_F/\dot{V}_E$ value of 0.86 is to be compared with the equivalent value (0.78) for the use of the EAR in anaesthetized children breathing spontaneously which was reported by Meakin and colleagues [2] and with data obtained during bench testing of the EAR in which the onset of rebreathing occurred at $0.87\dot{V}_E$ [9].

This method, whilst not suitable for routine monitoring of patients, is useful in that it does not (unlike the Kain and Nunn criteria) rely on a physiological response to rebreathing. It demonstrates rebreathing at an early stage and is of potential value during the assessment of anaesthetic breathing systems in determining values of $\dot{V}_F$ which avoid rebreathing in the clinical situation.

In the present study, the mean $\dot{V}_F$ at which rebreathing occurred as determined by the Kain and Nunn criteria [5], was 62.3 (SEM 2.98) ml kg^{-1}. Unlike controlled ventilation, during which V_T is under the control of the anaesthetist, there is a wide variability in V_T seen in anaesthetized adult patients undergoing surgery whilst breathing spontaneously. This limits the value of recommendations for $\dot{V}_F$ to eliminate rebreathing in terms of ml kg^{-1} min^{-1} and management, as always, has to be guided by the clinical condition of the patient.

In conclusion, the results of this study indicate that the EAR may be used safely in anaesthetized, spontaneously breathing adults with a $\dot{V}_F$ of $0.86\dot{V}_E$ and thus support the view that the EAR may be regarded as a universal anaesthetic breathing system.

ACKNOWLEDGEMENTS

The EAR system was supplied by Ohmeda (BOC Healthcare). The study was supported by a SERC/DTI Teaching Company grant to the University of Manchester Department of Anaesthesia.

COMMENTARY

SPINAL EXTRADURAL ABSCESS: PURSUIT OF VIGILANCE

P. R. BROMAGE

SUMMARY

A case of delayed extradural abscess and quadriplegia after extradural steroids is presented. Nine other cases of extradural abscess from the literature are reviewed to illustrate the influence of continuity of hospital admission and informed surveillance on successful outcome when extradural infection arises after extradural medication. A Medic-Alert system is proposed as a means of improving vigilance and neurological outcome for patients at risk. Careful study of the cost-effectiveness of such a scheme is recommended. (Br. J. Anaesth. 1993; **70**: 471–473)

KEY WORDS

Anaesthetic techniques: extradural. Complications: extradural abscess, paralysis. Corticosteroids.

Correspondence columns of the journal have debated the appropriateness of extradural steroids in the management of chronic pain and the danger of extradural abscess and paralysis from immune suppression associated with their use [1–4]. The following case report of extradural abscess after extradural steroids is presented and compared with nine other cases of extradural abscess selected from the recent literature, to illustrate the common factor of vigilance that determines timely treatment and ultimate neurological outcome, regardless of the use of steroids. An early warning system to improve vigilance and outcome is proposed and discussed in terms of feasibility and cost-effectiveness.

CASE REPORT

In the early 1980s, a 61-yr-old woman attended a university-based pain clinic for relief of post-herpetic pain in the upper thorax. After a failed trial of transcutaneous nerve stimulation (TENS), a preliminary extradural injection of 0.5% bupivacaine 5 ml was given at the third thoracic interspace. Segmental analgesia extended from T3 to T8, followed by subjective pain relief for 48 h. Three subsequent extradural injections of 0.5% bupivacaine with methyl prednisolone (Depo-Medrol) 40 mg at 1-week intervals gave excellent relief. All injections were carried out under full aseptic conditions. Surgical face masks were worn and fresh single-dose vials of medications were used on each occasion. The pain returned slowly and, 3 months later, a second course of weekly injections of extradural bupivacaine with methyl prednisolone was given and complete relief obtained.

One week after concluding the second course of injections, the patient undertook a long journey over rough country roads and fell asleep in the back of the car. She awoke with interscapular pain and attributed the pain to muscle strain from the car ride. The pain abated, but returned with increased intensity 3 days later. The next day she was admitted to a local hospital with a diagnosis of "possible facet syndrome" and she was treated by bed rest and pethidine for symptomatic pain relief. Four days after her admission, a consultant neurologist made a tentative diagnosis of extradural abscess. The temperature was slightly increased, to 37.4 °C. Lateral spinal tomograms of the second, third and fourth thoracic vertebrae appeared normal. Expectant treatment continued for a further 2 days. Painful spasms of the arms began on the sixth day after admission. Two days later, and 10 days after admission, a CAT scan and myelogram were performed, revealing a blocked thecal canal in the lower cervical region and quadriplegia developed immediately afterwards. Finally, urgent laminectomy was carried out and the underlying extradural abscess drained, but paralysis persisted.

Table I summarizes the present case and nine other reported cases of extradural abscess associated with extradural analgesia [5–13]. Five arose after extradural steroid injections and four after extradural local anaesthetics without steroids. The incubation period between the assumed date of infection and the appearance of localizing symptoms varied widely, between 4 and 40 days, with a tendency for patients with diabetes or corticoid medication to exhibit the longest intervals. In nine of the 10 patients, the final crescendo sequence of warning signs (increasing pain, neck stiffness, paraesthesiae and root pain) preceded paralysis by an interval of 36–72 h and in one patient (No. 10) by 10 days.

Table II shows the relationship between suspicion of extradural abscess and neurological outcome in the 10 patients reviewed. Absence of awareness of danger was characterized by management at home or in a facility different than the original treating hospital, or by written testimony from the reporting author, as in patient No. 10. A high index of diagnostic suspicion was present with four patients (Nos 3, 4, 8, 9) and all four made a complete recovery. A low level of suspicion appears to have existed with six patients (Nos 1, 2, 5, 6, 7, 10) and all six of these suffered permanent paralysis.

COMMENT

Extradural abscesses have been reported most commonly in the absence of anaesthesia [12–14] and after general anaesthesia [15], after locally invasive procedures such as lumbar puncture [16], spinal anaesthesia [17] or after extradural analgesia, as in the 10 cases reviewed. In one series of 35 abscesses treated aggressively by antibiotics, laminectomy, or both, fever was suppressed and neurological outcome affected adversely by prior administration of systemic steroids [14]. Although there is no statistical evidence to support a cause-and-effect relationship when extradural abscess follows invasive spinal procedures carried out under full aseptic precautions, there is a natural tendency to assume one. While such *post hoc, ergo propter hoc* reasoning may be illogical and groundless, it carries the inherent advantage of heightening awareness among medical attendants and of placing extradural abscess securely on the diagnostic agenda if a spinal procedure is known to have been performed. Signs that might have been given scant attention, especially when attenuated in immune-compromised patients, as in patient No. 1, are noted and given due weight, and the chances of cure by timely diagnosis and definitive treatment are improved.

The crucial clues may not be transmitted or received and correctly interpreted, however. Table II suggests that, while patients under continuous management by the same medical personnel are likely to escape adverse sequelae, because all the information is readily available for early diagnosis and treatment, those admitted to different hospitals may not fare so well. Patient No. 1, although an extreme example, illustrates the common pattern of inadequate information, delayed diagnosis and aimless drift to irrevocable tragedy. The patient had become unaware of a cause-and-effect relationship in the long interval between the extradural steroids and the onset of her new and apparently unrelated pain. Apparently, no history of extradural puncture or immune compromise was available at the hospital of re-admission until too late. In patients Nos 2, 5, 6 and 7, circumstances of discharge and re-admission were less florid, but qualitatively similar, and contributed to lesser degrees of delay, but enough to overrun the brief and final "period of grace" before irreversible neurological damage occurred.

Thus the pattern of events surrounding this review of some published cases seems to indicate a need to improve the follow-up process of patients who may be at risk of extradural abscess after invasive spinal procedures. As verbal informed consent procedures cannot be relied upon to educate patients about the intricacies of remote but catastrophic risks, some mandatory objective warning system is required. This could take the form of a Medic-Alert bracelet

(Medic-Alert Foundation, 12 Bridge Wharf, Caledonian Road, London N1 9UU), stamped with the date and the procedure done and to be worn continuously for 8 weeks after the last intervention.

At first sight such a warning system appears desirable, simple and reasonably cost-effective, but there are hidden expenses that might make it economically unworkable. Inevitably, the heightened sense of danger created by the early warning system will cause false alarms. Each of these is likely to result in re-admission to hospital and full investigation, including bacterial cultures of blood, sputum and urine, together with relevant imaging of the spine. Magnetic resonance imaging (MRI) is the most appropriate, sensitive and least invasive imaging technique currently available, at a present cost of approximately £900 sterling for a full spinal survey. Although MRI is highly sensitive, its specificity is not sufficiently developed to distinguish between blood and pus, for example after an extradural blood patch, and so other sophisticated scanning techniques may be invoked, including labelled leucocyte scans and possibly myelography, bringing the aggregate cost of each false alarm to several thousand pounds sterling. Assuming a 10 % false alarm rate (a not unreasonable estimate in Britain, but an underestimate for litigiously-inclined North America), a national risk load of 10000 patients would require an annual insurance budget of several million pounds to cover the cost of false alarms alone.

A more subtle financial disincentive to an early warning system lies in its medico-legal implications. Regardless of whether or not the system was successful in increasing the standard of care, the very existence of such a mechanism would alert plaintiffs' attorneys to a rich prize in all failures, or alleged failures, to meet the new standard. Physicians involved in any case of neurological sequelae to extradural abscess would be in legal jeopardy on the grounds that the proximate physician abandoned the patient or was negligent in his duty to provide the timely warning that could have prevented permanent damage [18]. As any anticipated salvage gains from timely diagnosis and averted paraplegia is not so easily susceptible to quantification, the net monetary effects of an early warning system cannot be calculated in simple financial terms.

These positive and negative factors need to be studied carefully before implementation of the long-standing view that prescient awareness and early diagnosis are essential to avoid tragic outcome in spinal extradural abscess [15, 16, 19–21]. Analogous problems of cost-effectiveness involving rare but catastrophic anaesthetic events have been faced successfully in other rare conditions, such as malignant hyperthermia and porphyria, and so the profession should be encouraged to apply equal vigour and wisdom in addressing the anaesthetic-related hazards of extradural abscess.

COMPARISON OF SPONTANEOUS SIGHS AND MANUAL INFLATIONS IN ANAESTHETIZED PATIENTS BREATHING AIR AND OXYGEN

A. C. DOW* AND N. W. GOODMAN
University Department of Anaesthesia, Southmead Hospital, Bristol

The breaths after a sigh, or augmented breath [1], have a smaller tidal volume and shorter inspiratory time than the breaths preceding it [2]. We have investigated some of the factors that cause these changes. We compared natural sighs, which we term "active sighs", with manual inflations ("passive sighs") in patients breathing air and hyperoxic mixtures of either 33% oxygen in nitrous oxide or 100% oxygen.

Patients of slim build and with easily manageable airways were included in the study. We studied 19 ASA I patients (16 women), aged 23–52 yr and weighing 49–83 kg. Patients were premedicated with a benzodiazepine if desired ($n = 9$).

Patients were monitored by pulse oximetry. Anaesthesia was induced with propofol and a laryngeal mask was inserted. Anaesthesia was maintained by a three-step reducing infusion of propofol stepped at 10-min intervals but the interval was prolonged if patients were clinically lightly anaesthetized. Patients started by breathing air and later breathed a hyperoxic mixture, from a Mapleson A system with flows of at least 10 litre min^{-1}. If patients sighed, we attempted to administer a matching passive sigh of the same tidal volume; otherwise we aimed for a passive sigh approximately 2.5 times the average tidal volume. Ventilatory variables were measured by inductance plethysmography. Continuous output from a capnograph was recorded.

The 10 breaths preceding and 20 breaths succeeding sighs were analysed in groups of five breaths, normalized for each sigh to a baseline taken as the mean of the group of five breaths before the sigh. Statistical comparisons were made on the first group of five after the sigh.

We analysed 33 active sighs, averaging 270% of baseline, and 37 passive sighs (262% of baseline). Tidal volume was reduced by an active sigh (95% confidence intervals of means 88–97% of baseline) or a passive sigh (89–95%). Sighs when breathing air had more effect than sighs during hyperoxia: with 100% oxygen, for active sighs the difference was 14% (3–25%); for passive sighs 10% (3–17%). There were no differences as a result of nitrous oxide. Active sighs shortened inspiratory time to 92% (90–94%), passive sighs to 98% (96–99%); we could not distinguish any effect of gas mixture.

We conclude that part of the decrease in tidal volume after a sigh is caused by transient chemical changes. The shortening of inspiratory time is either programmed in the respiratory centre when the sigh is generated, or caused by mechanoreceptor input not mimicked by manual inflation.

HYPERBARIC DECOMPRESSION BUBBLE FORMATION—BUILDING ON THE MAPLESON MODEL OF GAS DYNAMICS

V. FLOOK, O. EFTEDAL AND A. O. BRUBAKK
Department of Biomedical Sciences, University of Aberdeen, Aberdeen, Sintef Unimed, Trondheim and Department of Biomedical Engineering, University of Trondheim, Trondheim, Norway

In recent years the aim of those concerned with performing safe decompressions has changed from symptom-free decompressions to bubble-free decompressions, as evidence increases that symptomless dives can produce bubbles and bubbles may cause long-term damage to health. The basis for bubble formation is the partial pressure of inert gas in tissues and blood. The Mapleson model of inert gas uptake [1] provides an ideal means of calculating gas partial pressures during both uptake and washout of inert gas during diving and subsequent decompressions.

To this basic model has been added the concept of "inherent unsaturation". This means that as oxygen partial pressure decreases to less than arterial levels, bubble formation is prevented because the total pressure of dissolved gases is less than environmental pressure, unless the tissue is supersaturated with inert gas. Total gas content is calculated for tissue in equilibrium with venous blood throughout the decompression.

It is assumed that when there is sufficient gas to form a bubble, bubbles have formed. A simplistic model of bubble dynamics is used to plot the change in size of the bubbles from inception until they are finally resolved.

We compared the results from the model with pulmonary artery bubble counts in pigs using transoesophageal ultrasonic scanning

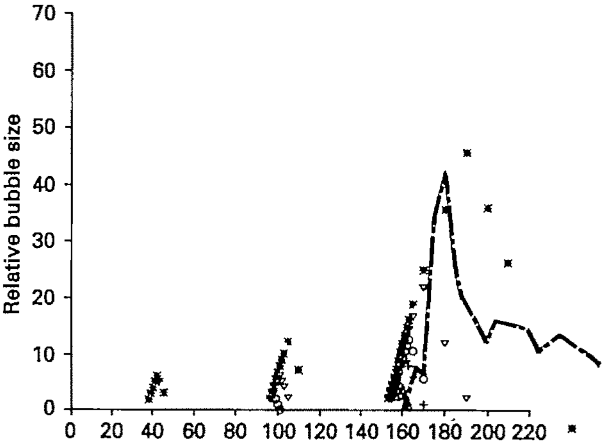

FIG. 1. Bubble count (broken line) compared with relative bubble size in the five fastest compartments of the Mapleson model: time constants 0.86 (△); 1.97 (+); 3.1 (○); 5.3 (▽); and 12.3 (✱).

and early results indicate that the model predicts considerable bubble growth for the decompression profiles in which many bubbles were detected. Figure 1 compares bubble count with predicted bubble size in the five fastest compartments of the Mapleson model. We do not yet know what the relative bubble size means in terms of real physical size, neither do we know the origin of bubbles which are detected in the pulmonary artery. This combined theoretical and experimental approach, together with inert gas quantification techniques developed by Mapleson's team in the early 1960s, should provide much needed information about the formation of bubbles during decompression.

EFFECT OF THREE DIFFERENT SURGICAL PRONE POSITIONS ON LUNG VOLUMES IN HEALTHY, AWAKE VOLUNTEERS

N. HENNESSY*, R. P. MAHAJAN* AND
A. R. AITKENHEAD
University Department of Anaesthesia, Queen's Medical Centre, Nottingham

Anaesthetists have long recognized that the prone position for surgery can cause respiratory embarrassment. Surgeons vary in their choice of prone position. The different prone positions demanded by surgeons may result in varying degrees of change in lung volume.

Three different prone positions used commonly by surgeons for back surgery were studied in 10 healthy volunteers (eight males) with a mean age of 31.1 yr (range 26–36 yr), mean weight of 69.4 kg (range 52–84 kg) and mean height of 1.73 m (range 1.6–1.8 m). Each volunteer was placed in the optimal operating position, in the same order, by the same surgeon according to his normal practice. The three positions were: (1) using two padded supports for the thorax and pelvis with the abdomen free; (2) using a preformed laminectomy support (Eschmann); (3) the knee–chest position.

The prone position without support was used as a baseline control. Lung volumes using helium dilution were calculated for each awake volunteer in each position. These were: functional residual capacity (FRC), residual volume (RV), expiratory reserve volume (ERV), inspiratory capacity (IC), slow vital capacity (SVC) and total lung capacity (TLC).

TABLE I. *Mean* (SD) *values for lung volumes in the four different prone positions*

	Two supports	Frame	Knee–chest	Control
FRC	2.85 (0.66)	3.15 (0.77)	3.83 (0.87)	2.77 (0.79)
RV	1.45 (0.47)	1.63 (0.49)	1.94 (0.48)	1.56 (0.48)
ERV	1.39 (0.14)	1.51 (0.14)	1.88 (0.22)	1.21 (0.16)
IC	3.40 (0.65)	3.40 (0.74)	3.01 (0.71)	3.59 (0.59)
TLC	6.25 (1.05)	6.51 (0.97)	6.84 (1.06)	6.36 (1.06)
SVC	4.78 (0.73)	4.88 (0.70)	4.89 (0.75)	4.80 (0.77)

The greatest increase in lung volumes was associated with the use of the knee–chest position (table I). Changes in FRC ($P < 0.001$), ERC ($P < 0.01$), RV ($P < 0.05$) and TLC ($P < 0.05$) were significant. Both FRC ($P < 0.01$) and ERV ($P < 0.05$) increased significantly in the frame position. No advantage was gained in comparison to the control position when two supports were used for the thorax and pelvis, and lung volumes were not significantly different from control values. We conclude that of these three prone positions in awake volunteers, the knee–chest position causes least respiratory restriction.

EFFECT OF SELECTIVE CELL SEPARATION ON RESPIRATORY FUNCTION AFTER AORTIC ANEURYSM SURGERY

M. McKAVNEY, R. J. CORSON, A. HANBURY,
A. J. MORTIMER, M. KEEGAN, C. N. McCOLLUM AND
I. T. CAMPBELL
University Departments of Anaesthesia and Surgery, Withington Hospital, Manchester

Hypoxaemia after abdominal surgery is caused by reduction in lung volume secondary to abdominal pain [1] but is also associated with platelet aggregation in peripheral veins and pulmonary embolization [2]. The effect of selective haemodilution on ventilatory function one week after elective aortic aneurysm surgery was investigated.

Twenty-two patients for aortobifemoral graft were randomized for selective haemodilution ($n = 11$) or normal treatment ($n = 11$). Selective haemodilution before operation removed 30% of circulating platelets, 15% of circulating granulocytes and decreased the concentration of haemoglobin by 2.3 g/dl. Cells were stored at room temperature and reinfused on wound closure. Volume was replaced with Gelofusine. Arterial $P\text{O}_2$, $P\text{a}_{\text{CO}_2}$, alveolar–arterial gradients ($P\text{A}_{\text{O}_2} - P\text{a}_{\text{O}_2}$) and lung volumes were measured before operation and nominally six days after operation. Several patients treated normally were not well enough on day 6 and were measured 6–9 (median 7) days after operation. Of the patients receiving haemodilution, 10 patients were studied 6, and one patient 7 days after operation ($P < 0.05$).

In the patients receiving haemodilution, $P\text{a}_{\text{O}_2}$ before operation was mean 11.9 (SD 1.6) kPa and in the controls 12.0 (1.5) kPa: $P\text{a}_{\text{CO}_2}$ was 5.3 (0.5) kPa and 5.4 (0.5) kPa, respectively. There was no difference in lung volume. After operation, in the cell-separated group, $P\text{a}_{\text{CO}_2}$ decreased by mean 0.25 (SEM 0.07), $P\text{a}_{\text{O}_2}$ by 1.1 (0.36) and ($P\text{A}_{\text{O}_2} - P\text{a}_{\text{O}_2}$) increased by 0.33 (0.36) kPa, compared with the controls where $P\text{a}_{\text{CO}_2}$ decreased by 0.59 (0.16) kPa ($P < 0.1$ compared with cell-separated group), $P\text{a}_{\text{O}_2}$ by 1.9 (0.6) kPa ($P < 0.1$) and ($P\text{A}_{\text{O}_2} - P\text{a}_{\text{O}_2}$) increased by 2.1 (0.48) kPa ($P < 0.005$ compared with the cell-separated group). Total lung and functional residual capacities decreased by between 13 and 20% in both groups but there were no differences between the groups.

EFFECTS OF MORPHINE AND ITS METABOLITES ON OPIATE RECEPTOR BINDING AND CYCLIC ADENOSINE-3′,5′-MONOPHOSPHATE (cAMP) FORMATION IN HUMAN NEUROBLASTOMA CELLS

D. G. LAMBERT AND R. A. HIRST
University Department of Anaesthesia, Leicester Royal Infirmary

The biochemical effects of opioid receptor occupancy are well established and include hyperpolarization, inhibition of depolarization-induced calcium entry and inhibition of formation of the second messenger, cAMP [1]. We have investigated the effects of morphine and its metabolites (morphine-6-glucuronide (M6G) and morphine-3-glucuronide (M3G)) in comparison with fentanyl on opioid receptor binding and cAMP formation in intact SH-SY5Y neuroblastoma cells.

Opioid receptor binding was assessed using the non-selective opiate ligand [^{3}H]diprenorphine. Affinity (K_{50}) values were computed as described previously [2]. For cAMP accumulation, cells were incubated with the phosphodiesterase inhibitor IBMX, opioids and forskolin (to increase cAMP) for 15 min. cAMP was assayed by a radioreceptor method as described previously [3]. Data are presented as maximum and half-maximum (IC_{50}) percent inhibition of forskolin-stimulated cAMP formation.

Both morphine and fentanyl were equipotent in the receptor binding assay, but fentanyl was approximately seven-fold more potent than morphine in inhibiting cAMP formation, and was approximately twice as efficacious as morphine. M6G was approximately four-fold weaker than morphine in the receptor binding assay but was equipotent with morphine in inhibiting

TABLE II. *Mean* (SEM) *biochemical effects of morphine, morphine-6-glucuronide* (*M6G*), *morphine-3-glucuronide* (*M3G*) *and fentanyl* (n = 5–8). *Significant differences,* $P < 0.05$, *compared with:* * *morphine or fentanyl;* † *morphine or M6G*

Drug	K_{50} (nmol litre^{-1})	IC$_{50}$ cAMP (nmol litre^{-1})	Max. inhibition cAMP (%)
Morphine	96 (10)	193 (58)	29 (4)
M6G	393 (96)*	113 (40)	29 (3)
M3G	> 30000	> 30000	—
Fentanyl	99 (5)	27 (8)†	56 (5)†

cAMP formation: M3G was ineffective (table II). These data suggest that the different therapeutic profiles of morphine, M6G and fentanyl may involve changes in neuronal cAMP formation and subsequent cAMP-dependent protein phosphorylation.

EFFECT OF PROPOFOL ON NEUTROPHIL RESPIRATORY BURST

A. J. OGILVY*, S. M. WHITELEY*, M. J. KOWOLIK AND P. G. MURPHY

Department of Anaesthesia, Leeds General Infirmary

A major mechanism by which neutrophils destroy bacteria is via generation of reactive oxygen species, a process known as respiratory burst [1]. Thiopentone, Althesin and most inhalation anaesthetic agents interfere with this mechanism [2]. In this *in vitro* study we have examined the effect of propofol on this aspect of neutrophil function.

Neutrophil suspensions were harvested from blood donated by 15 healthy and 15 critically ill adults, and incubated with propofol 12.5, 25 or 50 μmol litre^{-1} or Intralipid as control. The respiratory burst was induced by adding the neutrophil stimulant N-formyl-L-methionyl-L-leucyl-L-phenylalanine (FMLP 10 μmol litre^{-1}) and measured using luminol-enhanced chemoluminescence. This was quantified as an integral of its intensity with time (mV s) and the results analysed using repeated-measures ANOVA. Individual groups were compared using a paired *t* test to which a Bonferoni correction was applied, and 95% confidence intervals for the differences between the means (95% CI).

Table III shows the concentration-dependent attenuation of FMLP-induced chemoluminescence by propofol. This was observed in the neutrophils prepared from both patients and healthy volunteers, although the baseline activity was significantly greater in the patient group ($P = 0.0002$, Mann–Whitney *U* test, 95% CI of difference between medians 6322–37639). We conclude that, *in vitro*, propofol interferes with the neutrophil respiratory burst.

CLONAL VARIATION IN RESPONSE TO ENFLURANE ANAESTHESIA WITH *DAPHNIA MAGNA*

A. P. MYLES*, P. CALOW* AND C. S. REILLY

Departments of Anaesthesia and Animal and Plant Sciences, University of Sheffield

A previous study has shown that the freshwater invertebrate *Daphnia magna* may be used as a model of the potency of inhalation anaesthetics [1]. We have since used *D. magna* to investigate several aspects which affect anaesthetic potency. Previous workers have used selective breeding of both mice and nematode worms based on their sensitivity to anaesthesia in an attempt to characterize anaesthetic sites of action [2, 3]. Daphnids reproduce by parthenogenesis producing clones. Genetic differences in response to a number of toxicants have been observed previously between clones of *D. magna*. In this study we have investigated the interclonal variation in the sensitivity to enflurane.

Three clones (F, C, PS-1), known to be genetically distinct, were used in the study. All animals were cultured under standard conditions at 20 °C and 2–6-week-old individuals were used. Standard anaesthetic flowmeters and Cyprane vaporizers delivered the enflurane in oxygen (1 litre min^{-1}). Enflurane concentrations were measured using a Datex Normac. The anaesthetic mixture flowed into two glass observation chambers through two aquarium pumps. The gas was bubbled through 200 ml of the same analytical grade water in which the animals were cultured. The chambers were enclosed in a glass water bath and maintained at a constant temperature of 20 °C. The bath was raised so the base of the observation chambers was clearly visible. The enflurane concentration was increased by increments of 0.1% and the animals were allowed to equilibrate for 1 h at each step.

TABLE IV. *Mean* (*95% confidence intervals*) EC_{50} *values for response to enflurane for the three clones at different ages*

	Age (weeks)		
Clone	2	4	6
F	1.067 (1.02–1.12)	1.631 (1.56–1.7)	1.575 (1.39–1.78)
C	1.116 (1.12–1.21)	1.587 (1.51–1.66)	1.382 (1.29–1.48)
PS-1	1.162 (1.09–1.23)	1.245 (1.18–1.32)	1.373 (1.31–1.44)

Anaesthesia was defined as lack of limb movement in response to a noxious stimulus (cold strong light source). The number responding to the stimulus at each concentration was recorded. Concentration–response curves and EC_{50} values were calculated from the results using the PC Pharm computer program (table IV).

Genetic differences in response to enflurane were observed. Clonal differences in response could be manipulated to provide a model which may be of use in studies of mechanisms of anaesthesia.

MEMBRANE ACTION OF VOLATILE ANAESTHETICS: EFFECT OF HALOTHANE ON MICROVISCOSITY

B. APPADU, D. J. ROWBOTHAM, R. GRIFFITHS, S. GRAHAM AND R. I. NORMAN
University Department of Anaesthesia, Leicester Royal Infirmary

Volatile anaesthetic agents have been shown to increase cell membrane fluidity [1]. However, the precise site of this change is unknown. We have studied the effects of halothane on microviscosity at specific sites within cell membranes.

Erythrocyte ghost membranes were prepared from the blood of 10 healthy volunteers by the method described by Niggli and colleagues [2] and stored at −70 °C. A series of n-(9-anthroyloxy) fatty acid probes were used to measure microviscosity [3]. Ghost membranes were equilibrated at 37 °C with air and 0.5%–4.0% halothane via a calibrated Fluotec 3 vaporizer for 15 min. Probes were then added to the membrane suspension and incubated for 30 min before measurement of fluorescence polarization by a Perkin–Elmer LS50 luminescence spectrometer.

Figure 2 shows the reduction in mean polarization intensity ($n = 10$) for each probe with increasing concentrations of halothane ($P < 0.01$, repeated measures MANOVA for paired data).

Halothane causes a dose-dependent decrease in membrane microviscosity throughout the lipid bilayer of erythrocyte ghost membranes. This change in microviscosity does not saturate within the range of clinical concentration of halothane. The generalized action of halothane on membrane dynamics may underlie functional changes in cellular membranes during anaesthesia.

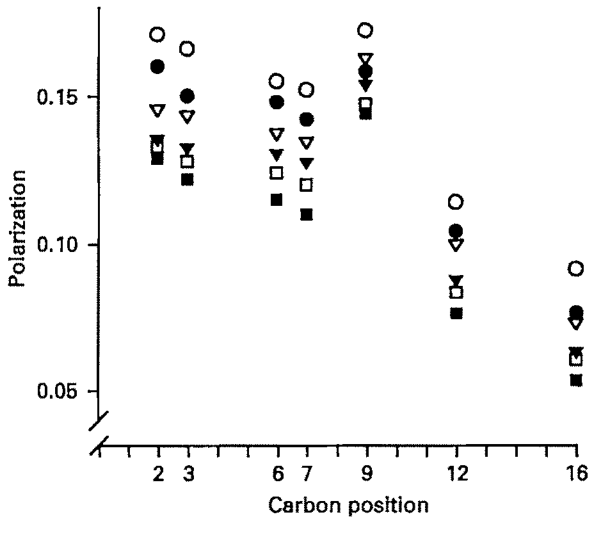

FIG. 2. Reduction in mean polarization intensity for each probe with air (○) and 0.5% (●), 1% (▽), 2% (▼), 3% (□), 4% (■) halothane.

ULTRASOUND MEASUREMENT OF MUSCLE THICKNESS IN THE ESTIMATION OF FAT FREE MASS

T. WATT, B. FARAGHER, D. J. WITHERS, R. E. ENGLAND, D. F. MARTIN AND I. T. CAMPBELL
Department of Anaesthesia, University of Manchester, Withington Hospital, Manchester

It is normal practice to regard the body as a two-compartment model—fat and fat free mass. Conventional techniques of assessing body mass [1] and composition rely either on complex apparatus, the administration of radioactive isotopes, or both, or they make assumptions which, in the critically ill patient retaining large amounts of fluid, are not valid. If the efficiency of nutritional support in multiple organ failure is to be evaluated, a technique of monitoring changes in fat free mass is needed which works in the presence of abnormal fluid retention.

The evidence is that in multiple organ failure, fluid is retained in subcutaneous and visceral tissue and not in the body of the muscle [2]. We have shown previously in 30 normal volunteers, a strong correlation ($r = 0.959$) between fat free mass (calculated from body weight and skinfold thickness) and total muscle thickness measured using ultrasound over six sites: the anterior thigh, forearm, biceps, triceps, rectus abdominus and the calf [3]. This compared favourably with the more conventional indices of lean body mass such as mid-upper arm circumference (0.789), arm muscle area (0.850) and arm muscle circumference (0.841).

Data on 70 normal volunteers has now been analysed, using linear multiple regression analysis, to determine what sites accounted for most of the variation. The correlation coefficient of fat free mass and total muscle thickness measured over biceps, thigh and forearm was 0.870. Adding height increased r to 0.922. For biceps and height alone, r was 0.919. The 95% confidence interval for the difference between the "true" and computed fat free mass was ±19.7%. These figures compare with r values for the same group of 0.737 for mid-upper arm circumference, 0.852 for arm muscle circumference and 0.854 for arm muscle area.

Measurement of total muscle thickness over biceps, front of thigh and forearm may provide a method of monitoring changes in body mass and composition as effective as measurements of arm circumference.

EFFECT OF LOCAL ANAESTHETIC CHOICE ON PLASMA CONCENTRATIONS OF CATECHOLAMINES DURING EXTRADURAL ANAESTHESIA

R. A. STEVENS*, D. BEARDSLEY* AND J. L. WHITE*
Departments of Anesthesiology, Uniformed Services University, Bethesda, Maryland, Medical College of Wisconsin, Milwaukee and Georgetown University, Washington, DC, USA

EXTRADURAL 0.07% BUPIVACAINE FOR POSTOPERATIVE PAIN

J. M. SLADE
Ronald Fisher Department of Anaesthetics, Poole General Hospital

It has been shown that in parturient women, analgesia obtained by infusing 0.25% bupivacaine 8 ml h^{-1} is inferior to that obtained by giving the same mass of drug as 0.07% bupivacaine 25 ml h^{-1} [1]. In this study, analgesia resulting from similar regimens is compared in patients undergoing abdominal aortic aneurysm repair.

All patients were operated on through a transverse incision and received extradural analgesia in the postoperative period. The patients were allocated randomly to one of two treatment groups. All were premedicated with lorazepam 1–2 mg and prochlorperazine 10 mg. Anaesthesia was induced with thiopentone and supplemented with doses of fentanyl up to 0.2 mg. Tracheal intubation was facilitated with vecuronium 8 mg and anaesthesia was maintained with enflurane or isoflurane in a mixture of nitrous oxide and oxygen. An extradural catheter was inserted at T9–11 and a bolus of 8 ml of 0.25% bupivacaine was given as an adjunct to anaesthesia. After surgery, the patients were transferred to the intensive care unit.

Patients in one treatment group received 0.25% extradural bupivacaine at 7 ml h^{-1}; patients in the other group received 0.07% bupivacaine 25 ml h^{-1}. All patients were given free access to i.v. boluses of alfentanil 0.05 mg given by a patient-controlled analgesia (PCA) device, the use of which had been explained to the patient on the day before surgery. The number of PCA doses received by the patient was used as a measure of the quality of the analgesia obtained from the extradural infusion.

Of the 35 patients who entered the study, 15 were withdrawn within 24 h; one patient had a fatal myocardial infarction, six were withdrawn because of protocol violations, four patients had no extradural block and four more were withdrawn when, despite demonstrable extradural blocks and frequent use of PCA alfentanil, they remained in pain. The latter four were in the 7-ml h^{-1} group. In the 20 patients who completed the study (10 in each group), the requirement for supplementary alfentanil was much lower (median three doses, range 0–16) in patients receiving bupivacaine 25 ml h^{-1} than in those receiving 7 ml h^{-1} (median 26.5 doses, range 0–50). The difference was statistically significant ($P < 0.01$, Mann–Whitney *U* test).

EFFECT OF STOPPING SMOKING ON UPPER AIRWAY REFLEXES

R. J. ERSKINE, P. J. MURPHY AND J. A. LANGTON
University Department of Anaesthesia, Leicester Royal Infirmary

Smokers are known to present problems to anaesthetists; in particular they seem more likely than non-smokers to suffer laryngospasm and cough on induction of anaesthesia [1]. In a pilot study [2], we found that the threshold concentration of ammonia vapour required to elicit reflex glottic closure (NH_3TR) in long-term smokers was significantly lower than that of non-smokers, indicating a much greater upper airway reflex sensitivity in smokers. Furthermore, no change was found after 24 h abstinence. Therefore, the aim of this study was to determine the effect of a longer period of abstinence from smoking on upper airway reflex sensitivity.

Twenty-five subjects smoking 15 or more cigarettes daily were recruited. The baseline NH_3TR was measured in each subject using a technique described previously [3]; 13 subjects agreed to stop smoking, the remainder to carry on. Over the next 3–4 weeks, repeated measures of NH_3TR were made at regular intervals.

Eight subjects (four males), mean age 31.5 yr (range 23–51 yr), stopped smoking completely for the period of the study whilst eight others (three males), mean age 33.8 yr (range 23–48 yr), continued to smoke and acted as the control group. Nine subjects failed to complete the study.

All subjects who stopped smoking showed an increase in NH_3TR. In the majority of subjects this occurred within 7 days of stopping smoking (fig. 3).

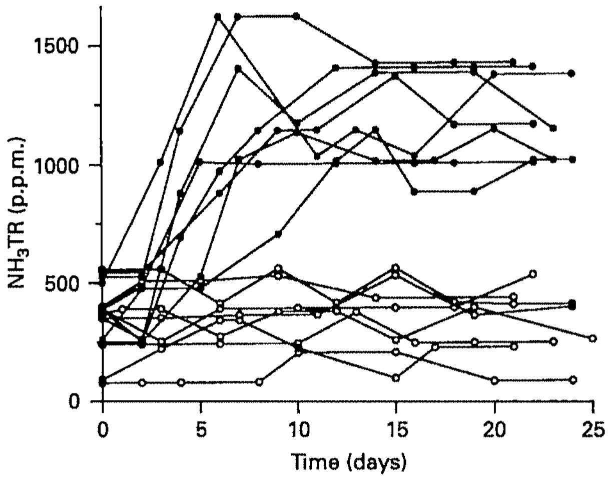

FIG. 3. Ammonia threshold concentration (NH_3TR) in smokers (○) and those who stopped smoking (●).

In conclusion, we have found that on stopping smoking there is a change in upper airway reflex sensitivity when tested using an ammonia stimulus.

POSTOPERATIVE LARYNGEAL FUNCTION ASSESSED BY TUSSOMETRY

J. M. LAMB*, G. E. MURTY*, R. M. SLATER AND A. R. AITKENHEAD
University Department of Anaesthesia, Queen's Medical Centre, Nottingham

Laryngeal function may be affected significantly after general anaesthesia [1]. A new non-invasive method of assessing laryngeal function by analysis of cough airflow waveform (tussometry) was used to determine if this is true.

The airflow waveform produced by a normal voluntary cough into a modified anaesthetic face mask was measured by a pneumotachograph linked to a Gaeltec flowmeter and displayed graphically as cough flow rate (litre min^{-1}) against time (ms). A normal airflow waveform shows a rapid increase to a peak—the cough peak flow rate (CPFR). The time taken to reach CPFR—the peak velocity time (PVT)—has been shown to correlate with laryngeal function in normal patients and those with vocal cord pathology [2].

Twenty unpremedicated ASA I patients undergoing peripheral orthopaedic surgery were studied. Before induction of anaesthesia, three airflow tracings were obtained in the sitting position. The shortest PVT and maximum CPFR were recorded. General anaesthesia was induced with propofol 2.2–3.8 mg kg^{-1} and fentanyl 0–1.9 µg kg^{-1} and maintained with 1–2% enflurane and 60% nitrous oxide in oxygen, administered via a laryngeal mask airway (LMA). After operation, the LMA was left *in situ* and the time (T0) of spontaneous rejection of the LMA, eye-opening, or both, was recorded.

TABLE V. *Mean difference (ms) in PVT from baseline*

Time (min)	Difference	*P* value
T10	20.90	0.0001
T20	8.95	0.0019
T30	9.27	0.02

Tussometry was performed at 10 min (T10) and 20 min (T20). Recordings were also taken at 30 min (T30) in patients with a prolonged PVT at 20 min. Differences in PVT and CPFR were compared using Student's *t* test and 95% confidence intervals for the mean differences were calculated.

Mean (SD) baseline PVT was 25.5 (4.8) ms before anaesthesia. After anaesthesia, PVT was prolonged in 19 patients at T10, in 11 patients at T20 and in five patients at T30 (table V). CPFR did not change significantly after anaesthesia. These results may reflect a temporary depression of laryngeal function associated with recovery from general anaesthesia.

ADDITION OF DROPERIDOL TO PATIENT-CONTROLLED ANALGESIA: EFFECT ON NAUSEA AND VOMITING

O. A. WILLIAMS*, F. L. CLARKE*, R. W. HARRIS*, P. SMITH* AND J. E. PEACOCK
Departments of Anaesthesia, Bassetlaw Hospital and Sheffield University Medical School

Patient-controlled analgesia (PCA) with morphine is associated with postoperative nausea and vomiting (PONV) [1]. Droperidol and morphine are stable mixed in plastic syringes for infusion [2]. The aim of this study was to assess the effect of adding droperidol to PCA morphine on PONV and antiemetic requirement.

After local Ethics Committee approval, 60 healthy female patients (aged 28–67 yr) undergoing abdominal hysterectomy were included in the study. All patients were premedicated with temazepam 20 mg and a standard anaesthetic with propofol 2 mg kg^{-1}, vecuronium 0.1 mg kg^{-1}, morphine 10 mg, droperidol 2.5 mg, 66% nitrous oxide and up to 2% isoflurane in oxygen was administered. Patients were randomized to receive either morphine 2 mg ml^{-1} (group 1) or morphine 2 mg ml^{-1} plus droperidol 0.2 mg ml^{-1} (group 2) via a Graseby PCA system with a 0.5-ml bolus and a lockout period of 5 min. All patients were prescribed rescue medication of prochlorperazine 12.5 mg 8-hourly as required. Observations were made at 4, 12 and 24 h after operation. These included four-point verbal rating scores (VRS) of nausea, vomiting, pain and sedation by one or two blinded observers. At follow-up, requirement for prochlorperazine in the 24-h study period was recorded.

Fifty-six patients completed the study, 27 in group 1 and 29 in group 2. The groups were similar in age, weight, morphine requirement and pain scores. Patients in group 2 had significantly decreased VRS for nausea at 12 h and less requirement for prochlorperazine (table VI). Sedation VRS at 24 h were significantly increased in group 2, however, no patient had to be withdrawn from the study because of sedation or other adverse effects.

TABLE VI. *Nausea, sedation and requirement for prochlorperazine in the two groups of patients.* *P < *0.05*

	Group 1	Group 2
% Patients with nausea (VRS = 0 at 12 h)	44.4	75.9*
% Patients with sedation (VRS = 0 at 24 h)	63.0	34.5*
% Patients given prochlorperazine	59.3	31.0*

Addition of low-dose droperidol to a morphine PCA reduced emetic symptoms at 12 h and decreased requirement for rescue antiemetic treatment. No adverse effects other than mild sedation were apparent.

RELATIVE EFFICACY AND POTENCY OF NALMEFENE, A LONG-ACTING OPIOID ANTAGONIST

N. A. WATSON, I. T. MUNDAY AND R. M. JONES
Academic Department of Anaesthetics, St Mary's Hospital Medical School, London

Nalmefene, an analogue of naltrexone, is a potent opioid antagonist with an elimination half-life of approximately 8 h [1]. This may prevent the delayed respiratory depression often observed when naloxone (elimination half-life approximately 1 h [2]) is used to antagonize the effects of long-acting opioids. We have determined the relative potencies of nalmefene and naloxone in antagonizing fentanyl-induced respiratory depression and assessed the clinical efficacy of nalmefene.

Thirty-six patients, ASA I–III, aged 20–72 yr undergoing major elective surgery, for which moderate doses of fentanyl 4–25 µg kg^{-1} were considered appropriate, were studied. A standardized anaesthetic technique was used, including premedication with morphine 0.1 mg kg^{-1}, induction with thiopentone, neuromuscular block with vecuronium and ventilation with low concentrations of isoflurane. After antagonism of residual neuromuscular block, the following criteria were used to assess the need for postoperative opioid antagonism: ventilatory frequency less than 16 b.p.m. while intubated; ventilatory frequency less than 12 b.p.m. extubated; or a rate of 12–16 b.p.m. with arterial oxygen saturation (Sa_{O_2}) greater than 3% less than before operation. Patients were allocated randomly to receive incremental doses of nalmefene 0.25 µg kg^{-1} or naloxone 0.5 µg kg^{-1} at 5-min intervals, titrated against ventilatory frequency and Sa_{O_2}, until respiratory depression was reversed.

TABLE VII. *Mean (range) potency and clinical efficacy of nalmefene compared with naloxone.* **P < *0.01 compared with nalmefene group*

	Nalmefene (*n* = 18)	Naloxone (*n* = 18)
Duration of surgery (min)	107.9 (28–231)	129.9 (43–289)
Total dose of fentanyl (µg kg^{-1})	10.40 (5.62–25)	10.46 (4.44–22.4)
Initial dose of antagonist (1st hour) (µg kg^{-1})	0.57 (0.25–0.75)	1.11** (0.5–2.5)
Morphine dose (1st hour) (mg)	10.28 (0–20)	6.53 (0–15)
Morphine dose (1–23 h) (mg)	8.06 (0–30)	7.22 (0–30)

The potency of nalmefene was found to be approximately twice that of naloxone (table VII). After the initial dose of antagonist, three patients who received nalmefene required a total of five additional doses compared with seven naloxone patients who required a total of 37 additional doses ($0.05 < P < 0.1$, Mann–Whitney test). This suggests that the antagonism of respiratory depression by nalmefene is of greater duration than that produced by naloxone. The failure of these results to achieve statistical significance probably reflects the small sample size.

ANQ 9040: EFFECT OF TWICE THE ED_{95} DOSE

I. T. MUNDAY* AND R. M. JONES
St Mary's Hospital Medical School, London

Anq 9040 is a competitive neuromuscular blocking drug with a rapid onset of action. An initial dose-finding study in 31 volunteers indicated a mild vagolytic action but no other adverse effects, and an estimated ED_{95} of 1.3 mg kg^{-1}. The aim of this study was to evaluate the effect of twice the ED_{95} dose of Anq 9040 in healthy volunteers.

Ten male volunteers were anaesthetized with a propofol infusion and ventilated with nitrous oxide in oxygen via a laryngeal mask airway. ECG, Sp_{O_2}, end-tidal carbon dioxide concentration, temperature and arterial pressure were monitored. The response of the adductor pollicis to train-of-four stimulation (12-s intervals) of the ulnar nerve was measured with a Myograph 2000. Plasma samples were obtained for histamine assay at 0, 2, 5, 10, 15 and 30 min after injection. Anq 9040 was administered over 30 s in the first seven volunteers and over 1 min in the final three volunteers. The onset time was measured from the end of injection to 100% block (i.e. 12 s after the last visible T1 response). The duration of action was measured from the end of injection until a T4/T1 ratio > 0.7.

The mean onset time for the first seven patients was 51.3 s (range 40–67 s). Mean duration of action ($n = 9$) was 45.3 min (range 35.6–60.8 min). Mean changes in heart rate, arterial pressure and plasma concentrations of histamine are shown in table VIII. At 2 min, heart rate had increased to 49 % greater than baseline and mean arterial pressure had decreased by 12%. Arterial pressure returned to baseline within 5 min but the heart rate remained increased for the duration of the experiment. Plasma concentrations of histamine were increased significantly at 2 and 5 min.

These results indicate that Anq 9040 is a rapid onset neuromuscular blocker. However, twice the ED_{95} dose is associated with significant histamine release.

TABLE VIII. *Mean (SD) changes in heart rate (HR), mean arterial pressure (MAP) and plasma concentrations of histamine after administration of Anq 9040.* *P < 0.05 (*paired* t *test*)

	Time (min)					
	0	2	5	10	15	30

COMPARISON OF THE ONSET OF DEPOLARIZING *VS* NON-DEPOLARIZING BLOCK AFTER EARLY TOURNIQUET RELEASE IN THE ISOLATED FOREARM

J. R. HOOD*, N. CAMPKIN* AND S. A. FELDMAN
Magill Department of Anaesthetics, Westminster Hospital, London

In a previous study of the onset of vecuronium block in the isolated forearm, it was noted that if the arterial tourniquet was released at 50 % twitch depression, the block continued to increase for a further 2–3 min. This was shown not to be a result of recirculating drug [1]. Feldman and Tyrrell [2] proposed that non-depolarizing drugs were bound in the neuromuscular junction, unlike depolarizing drugs, such as decamethonium, which dissociate rapidly. This would explain the prolonged recovery after non-depolarizing agents compared with decamethonium in the isolated forearm. It is possible that such binding may maintain a concentration gradient in the biophase after early tourniquet release and explain the further increase in block seen after vecuronium. If so, decamethonium block would not exhibit this phenomenon. We have studied the onset of block produced by vecuronium, decamethonium and atracurium in the isolated forearm, after early release of the tourniquet.

Three groups of five experiments were performed on five volunteers. A vein on the dorsum of the hand was cannulated, a 2-kg strain gauge with a thumbpiece modification was secured and a standard pretension applied. The ulnar nerve at the wrist was stimulated using a supramaximal 0.2-ms square wave impulse at 0.2 Hz. The resultant adductor pollicis twitch was amplified and recorded. After stabilization, a forearm tourniquet was inflated to a pressure of 300 mm Hg. Saline 20 ml containing either vecuronium 0.3 mg (group I), atracurium 2 mg (group II) or decamethonium 0.15 mg (group III) was administered i.v. to produce paralysis by retrograde spread. These doses are equipotent in the isolated forearm. The arterial tourniquet was released at approximately 50 % twitch depression in each group. The twitch height relative to control (T1/T0) at tourniquet release and at maximal block were measured and the difference calculated; the values for each group were compared using ANOVA (table IX).

TABLE IX. *Mean (SD) twitch height relative to control (T1/T0) at tourniquet release, at maximum block and the difference between the two in patients given vecuronium (group I), atracurium (group II) and decamethonium (group III).* **P < *0.01 compared with groups I and II*

	T1/T0 (%)		
Group	At release	Max. block	Difference
I	42 (4.9)	10 (3.8)	32 (6.6)
II	48 (2.2)	16 (4.7)	32 (5.9)
III	49 (3.4)	44 (6.8)**	5 (5.8)**

Onset of depolarizing block by decamethonium in the isolated forearm is associated with minimal increase in block after early tourniquet release. Significant increases in block after early tourniquet release are seen during onset of vecuronium or atracurium block in the isolated forearm and may be a result of binding of these drugs within the biophase.

RECOVERY OF ATRACURIUM AND VECURONIUM NEUROMUSCULAR BLOCK IN THE ISOLATED FOREARM

J.-C. LAW MIN*, J. R. HOOD*, N. CAMPKIN* AND S. A. FELDMAN
Magill Department of Anaesthetics, Westminster Hospital, London

The duration of action of systemic injections of three times the ED_{90} of atracurium or vecuronium are similar (58.3 *vs* 52.6 min)

[1]. This occurs despite the elimination half-life of vecuronium being approximately three times greater than that of atracurium (71 min *vs* 22 min, respectively, pooled data) [2]. This discrepancy has been attributed to the differing modes of elimination of the two drugs; atracurium undergoes multicompartment elimination via Hoffmann degradation and ester hydrolysis [2]. These processes might therefore be expected to produce a more rapid recovery of atracurium block in the isolated arm experiment. The purpose of this study was to compare the blocks produced by these two drugs in bilateral isolated arm experiments, both blocks being affected by the same, small plasma concentration of drug.

Eight experiments were performed in six volunteers. A vein on the dorsum of each hand was cannulated, a 2-kg strain gauge with a thumbpiece modification was secured and a standard pretension applied. The ulnar nerve at the wrist was stimulated using a supramaximal 0.2-ms square wave impulse at 0.2 Hz. The resultant adductor pollicis twitch was amplified and recorded. After stabilization, forearm tourniquets were inflated simultaneously to pressures of 300 mm Hg. Vecuronium 0.3 mg was administered i.v. into one arm and atracurium 1.5 mg into the other. Both drugs were given in saline 20 ml to produce paralysis via retrograde spread. These doses are equipotent: 0.11 of an ED_{95} dose for a 70-kg subject. The arterial tourniquets were released together after 3 min: > 90 % twitch depression was achieved in each experiment. The 25–75 % recovery indices were measured from each hard copy and the values of the two groups compared by paired *t* test.

The mean recovery indices were significantly larger ($P < 0.01$) for atracurium (mean 11.0 (SD 1.7) min) compared with vecuronium (9.2 (0.9) min).

The results were converse to expectation. The prolonged recovery of atracurium in the isolated arm is consistent with this drug being washed more slowly out of the biophase of the arm than vecuronium, as a result of stronger affinity for binding sites within the biophase. After a systemic injection of atracurium, it is possible that this greater affinity is offset by the more rapid decrease in plasma concentrations than that of vecuronium, and the resulting greater biophase–plasma concentration gradient, so that its overall duration of action equals that of vecuronium.

PREDICTION OF INFUSION RATE OF VECURONIUM TO MAINTAIN STEADY STATE USING THE BOLUS TEST DOSE TECHNIQUE

R. J. MORGAN AND B. J. POLLARD
Department of Anaesthesia, Manchester Royal Infirmary

A previous study [1] has demonstrated that it is possible to predict the infusion rate of vecuronium required to maintain steady state neuromuscular block by measuring the duration of action of a 4-mg bolus dose given in the presence of existing vecuronium block. That study used a Relaxograph (Datex) to measure twitch height, and provided data only for infusion rates between 2.0 and 4.0 mg h^{-1}. Therefore, we decided to re-examine this technique using a standard peripheral nerve stimulator to measure the interval between return of T1 after the loading dose and bolus dose in order to predict infusion rate.

Neuromuscular block was monitored first by a Relaxograph on the hand (the display of which was out of sight of the observer) and also by observing the movement of one great toe after stimulation of the lateral popliteal nerve. Vecuronium 0.1 mg kg^{-1} was given and on return of the first contraction of the train-of-four, a bolus of vecuronium 1, 2 or 4 mg was given. On return of the first contraction of the train-of-four again, an infusion of vecuronium was begun at a rate predicted from Harrison's study [1]. Adjustments were then made to obtain a constant level of block.

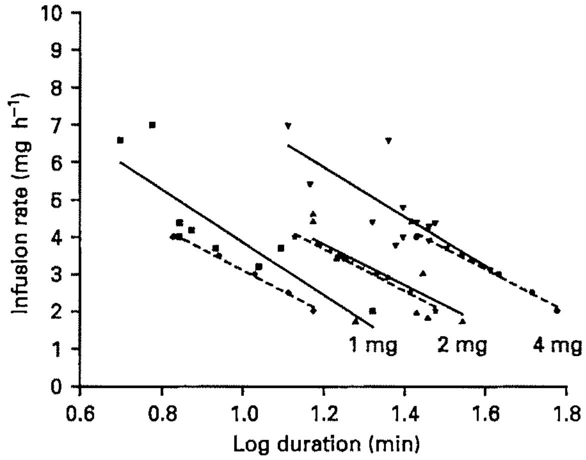

FIG. 4. Duration of action of a test dose of vecuronium when given before the infusion, compared with the infusion rate. — — — = Data from Harrison's study [1].

Results are shown in figure 4. Use of the 2-mg and 4-mg bolus test doses was not technically difficult. However, when a 1-mg bolus dose was given during the recovery phase of neuromuscular block, the difference in degree of block was imperceptible by palpation. The Relaxograph data were used for the 1-mg bolus dose.

This technique is useful for predicting the infusion rate of vecuronium during anaesthesia.

ONSET OF ACTION OF A SMALL DOSE OF VECURONIUM

M. H. NATHANSON, C. A. McCARTNEY, C. FERGUSON AND M. J. JORDAN
Department of Anaesthesia, St Bartholomew's Hospital, London

Individual variation in the effect of a weight-based dose of a non-depolarizing neuromuscular blocking agent is well described. In 1967, Katz described the effect of a small dose of tubocurarine 0.1 mg kg^{-1} in 100 patients in which the degree of block produced varied from 0 to 100 % [1]. We studied the onset of action of vecuronium in doses equivalent to those used by Katz.

After Ethics Committee approval, informed consent was obtained from 50 healthy adult patients (26 males) aged 31–61 yr (median 45 yr) undergoing elective surgical procedures. Patients received standardized premedication and anaesthesia. Patients' lungs were ventilated to maintain end-tidal carbon dioxide concentration ($P\bar{E}'_{CO_2}$) between 4.5 and 6.2 kPa. $P\bar{E}'_{CO_2}$ and end-tidal enflurane were measured with a Datex Capnomac, and palmar skin temperature was measured with a Libra Oxygen and Temperature Monitor Model 900. A Datex Relaxograph was used to measure the electromyograph response over the hypothenar eminence of stimulation of the ulnar nerve. After calibration of the Relaxograph, the control response to a supramaximal stimulus was measured and vecuronium 0.02 mg kg^{-1} was given by bolus injection. The height of the first twitch of the train-of-four, $P\bar{E}'_{CO_2}$, end-tidal enflurane and skin temperature were measured after 5 min. The results were analysed using the StatView II (Abacus Concepts) statistical package.

The measured response of the first twitch in the train-of-four to the control response (T1/T0) ranged from 0 to 100 % (median 70 % (51–83 % interquartile range)) (fig. 5). We found no significant correlation between T1/T0 and $P\bar{E}'_{CO_2}$, end-tidal enflurane or skin temperature. There was a weak negative correlation with weight ($\rho = -0.34$, $P = 0.016$) and a weak positive correlation with age ($\rho = 0.39$, $P = 0.006$) (Spearman's rank correlation coefficient).

We have demonstrated that there is wide individual variation to

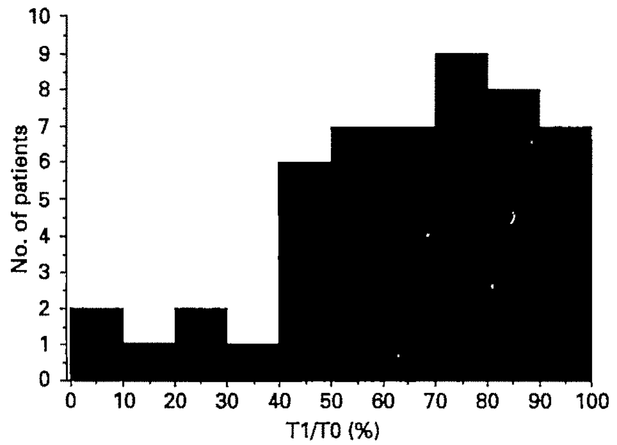

FIG. 5. Frequency distribution of T1/T0 at 5 min.

a small dose of vecuronium when the dose is calculated on a weight basis. The weak negative correlation between T1/T0 at 5 min with body weight confirms that a dose based on body weight alone tends to overestimate vecuronium requirements in heavy patients. The weak positive correlation with age may be spurious, as the block may still be developing at 5 min in the elderly patient, but more studies are necessary to confirm this. These findings may be of clinical significance when small doses of vecuronium are used for "priming".

PHARMACOKINETICS OF ROCURONIUM (ORG 9426) IN PATIENTS WITH AND WITHOUT IMPAIRED RENAL FUNCTION

R. COOPER, V. R. MADDINENI, R. K. MIRAKHUR
AND J. M. K. H. WIERDA
Departments of Anaesthesia, The Queen's University of Belfast and the University of Groningen, The Netherlands

Rocuronium (Org 9426) is a new monoquaternary aminosteroidal neuromuscular blocking agent with a duration of action similar to that of vecuronium but with a faster onset of effect [1]. Although studies in the cat have suggested the drug to be primarily excreted via the liver [2], studies by Wierda and colleagues showed that approximately 30 % of an injected dose of rocuronium is excreted by the kidneys in man [3]. In the present study we have determined the pharmacokinetics of a single bolus dose of rocuronium in patients with and without impaired renal function.

Nine patients with normal renal function and nine with chronic renal failure requiring haemodialysis were included in the study. Anaesthesia was induced with fentanyl 2–3 μg kg^{-1} and thiopentone 3–5 mg kg^{-1} and maintained with 67 % nitrous oxide in oxygen and 0.5–1 % isoflurane (inspired concentration). Neuromuscular block was measured by stimulation of the ulnar nerve with supramaximal stimuli of 0.2-ms duration, in a train-of-four (TOF) mode at 2 Hz every 1 s, and recording the force of contraction of adductor pollicis muscle. Rocuronium 0.6 mg kg^{-1} was administered after stabilization of the control responses. Venous blood samples were obtained before injection of rocuronium and at intervals for 390 min. Plasma concentrations of rocuronium were measured by high performance liquid chromatography. The data were fitted to a three-compartment model using the program Multifit. Data from one patient from each group were excluded from analysis. The results were compared using the Mann–Whitney *U* test.

TABLE X. *Mean* (SD) *pharmacokinetic variables in patients with renal failure and in control subjects.* *P < *0.05*

	Renal failure	Controls
n	8	8
Cl (ml kg^{-1} min^{-1})	2.5 (1.1)*	3.7 (1.4)
$T_{\frac{1}{2}}^{\pi}$ (min)	1.6 (0.7)	1.8 (1.5)
$T_{\frac{1}{2}}^{\alpha}$ (min)	24.3 (11.1)	14.8 (5.5)
$T_{\frac{1}{2}}^{\beta}$ (min)	104 (41.0)	97 (26.4)
V^{ss} (ml kg^{-1})	212 (47.3)	207 (48.9)
V^{c} (ml kg^{-1})	51.0 (29.2)	38.5 (21.1)
MRT (min)	97 (48.9)	58 (9.6)

The time to spontaneous recovery of T1 to 90 % of control were 101 and 69 min and to recovery of TOF ratio to 0.7, 99 and 73 min, respectively, in patients with and without renal failure ($P > 0.05$). The results of kinetic analysis are summarized in table X. Renal failure was associated with a decrease in the clearance of rocuronium, but other pharmacokinetic variables were not significantly different between the groups. This may explain the slightly longer duration of action of rocuronium observed in patients with renal failure.

LUNG FUNCTION AFTER VECURONIUM PRETREATMENT IN ELDERLY PATIENTS

R. P. MAHAJAN*, N. HENNESSY* AND
A. R. AITKENHEAD
University Department of Anaesthesia, Queen's Medical Centre, Nottingham

Pretreatment with vecuronium 0.01 mg kg^{-1} in young, healthy adults causes significant reductions in forced vital capacity (FVC), forced expiratory volume in 1 s (FEV_1), maximum mid-expiratory flow rate (MMEF), functional residual capacity (FRC) and expiratory reserve volume (ERV), although oxygen saturation ($S\mathrm{p}_{\mathrm{O}_2}$) remains unchanged [1]. This study was carried out to investigate the effect of the same pretreatment on lung function in elderly patients and to identify any clinical evidence of muscle weakness.

Informed consent was obtained from eight female patients (ASA I–II) aged 67–76 yr (mean 72.2 yr), height 1.51–1.69 m (mean 1.58 m) and weight 56–72 kg (mean 64.8 kg). Premedication comprised temazepam 10 mg, 45–60 min before surgery. The investigation was carried out in the anaesthetic room with patients in the supine position. ECG and arterial oxygen saturation were displayed continuously. Lung function (FVC, FEV_1, MMEF,

TABLE XI. *Mean* (SD) *results of lung function tests before and after administration of vecuronium.* *P < *0.05;* **P < *0.01;* ***P < *0.001*

	Before	After	% Change
FVC	2.17 (0.36)	1.97 (0.37)**	−9.6

PEFR	3.15 (1.42)	3.38 (1.52)	+9.8
MMEF	2.02 (0.61)	1.89 (0.50)	−1.3
FRC	2.35 (0.62)	1.90 (0.49)**	−18.05
ERV	0.43 (0.22)	0.19 (0.12)***	−57.7
RV	1.92 (0.56)	1.71 (0.51)	−9.8
IC	2.23 (0.55)	2.19 (0.43)	−0.71
SVC	2.66 (0.56)	2.38 (0.53)*	−9.67
TLC	4.58 (0.69)	4.09 (0.63)*	−10.12
$S\mathrm{p}_{\mathrm{O}_2}$	96.60 (1.06)	93.88 (3.31)*	−2.75

peak expiratory flow rate (PEFR), FRC, ERV, residual volume (RV), inspiratory capacity (IC), slow vital capacity (SVC), total lung capacity (TLC) and Sp_{O_2}) was assessed using a Morgan transfer test machine before and 3 min after administration of vecuronium 0.01 mg kg^{-1} i.v. The results were analysed by paired Student's *t* test. All patients developed ptosis, six were unable to perform the Valsalva manoeuvre for 10 s, five had diplopia and three were unable to swallow or lift their head for > 4 s, demonstrating significant muscle weakness. Significant reductions occurred in FVC, FEV_1, FRC, ERV, SVC and TLC (table XI). Importantly, Sp_{O_2} decreased by > 4 % in four of the eight patients, causing a significant overall change.

We conclude that vecuronium pretreatment in elderly patients causes significant impairment of lung function and a significant decrease in oxygen saturation.

PROPOFOL AND ALFENTANIL OR THIOPENTONE AND SUXAMETHONIUM FOR TRACHEAL INTUBATION

G. N. BECK*, G. R. MASTERSON*, J. RICHARDS* AND P. BUNTING*
Department of Anaesthesia, Royal Preston Hospital, Preston

The routine technique for rapid sequence induction usually involves the use of thiopentone and suxamethonium. The many complications of suxamethonium are well recognized and so alternative techniques are desirable. In this study, we compared the intubating conditions and haemodynamic changes during induction of anaesthesia using a standard rapid sequence induction, using propofol and alfentanil.

Sixty-four patients (ASA I and II, aged 18–60 yr) undergoing surgical procedures lasting longer than 20 min and requiring tracheal intubation were studied. After assessment of pharyngeal structures using the Mallampati test [1], the patients were preoxygenated for 3 min. Arterial pressure (Dynamap), heart rate and oxygen saturation (Ohmeda 3700E) measurements were made 3 min before induction and at 1-min intervals from induction for 4 min.

Patients were allocated randomly to two groups. In group TS, anaesthesia was induced with thiopentone 5 mg kg^{-1} over 20 s, followed by suxamethonium 1 mg kg^{-1}. Tracheal intubation was performed 40 s after administration of suxamethonium. At tracheal intubation, fentanyl 2 μg kg^{-1} was given. In group PA, anaesthesia was induced with alfentanil 50 μg kg^{-1}, followed by propofol 2 mg kg^{-1} over 30 s. Tracheal intubation was performed after a further 30 s. Thus tracheal intubation occurred 1 min after commencement of induction in both groups.

Tracheal intubation was performed by a junior anaesthetist independent of the study who recorded intubating conditions on a visual analogue scale and the grade of intubation [2]. Occurrence of coughing, laryngospasm, movement, bronchospasm or other significant complication was recorded.

The groups were comparable in age, sex and weight. There was no significant difference between the Mallampati, Cormack and Lehane and visual analogue scores between the two groups (chi-square and Mann–Whitney tests). However, two patients in group TS did require a second dose of suxamethonium, and a third sustained initial oesophageal intubation. No such additional intervention was required in group PA. Group PA showed a significant decrease in arterial pressure and heart rate after induction, whereas group TS showed a significant increase in arterial pressure and heart rate (table XII).

We conclude that rapid tracheal intubation can be performed reliably using the regimen described, avoiding the use of suxamethonium. This technique may be of use in patients where a decrease in arterial pressure and heart rate is preferable to an increase in arterial pressure and heart rate during a rapid sequence induction and warrants further investigation.

VALIDATION OF COHERENT FREQUENCY OF THE EEG AS A MEASURE OF CONSCIOUSNESS DURING ANAESTHESIA

R. MUNGLANI*, J. ANDRADE*, D. J. SAPSFORD, A. BADDELEY* AND J. G. JONES
Cambridge University Department of Anaesthesia and MRC Applied Psychology Unit, Cambridge

The amplitude of the 40-Hz auditory steady state response (SSR) has been proposed as an indicator of consciousness during anaesthesia [1]. However, we showed that this signal disappears in awake subjects with very light anaesthesia [2]. We examined the relationship between the change in SSR and in cognition during the inhalation of a range of isoflurane concentrations.

The SSR was examined in response to a range of auditory clicks from 47 to 5 Hz, presented sequentially in seven subjects who inhaled end-tidal isoflurane concentrations increasing stepwise from 0–0.8 %. At two points in the study, a painful stimulus was given. During the study, category recognition (CR) and within list recognition (WLR) were used to test psychological function. After the study, implicit and explicit memory were tested for stimuli and events during the study period. At each stimulating frequency, 100 samples of EEG were recorded, averaged and a Fourier transform applied to obtain a frequency–power spectrum. Three components were seen: the fundamental (P*f*), and the first and second harmonics (P_1 and P_2). Analysis showed that at certain coherent frequencies (CF), the power in the fundamental was large with little power in the harmonics. Frequencies either side of the CF did not show this pattern. To extract these CF, a manipulation was applied so that if $(P_1+P_2) >$ 30 % P*f* then a value of 0 was given to P*f*, otherwise P*f* was left at its original value. Data were then transformed so that the resultant power, $P_r = (Pf/(P_1+P_2)) \times Pf$. If more than one CF appeared, a weighted average coherent frequency (aCF) was used.

There was a decrease in aCF, CR and WLR with increasing concentration of isoflurane. Painful stimulation caused an increase in all variables (ns). The aCF correlated best with WLR (r = 0.343, Spearman, P = 0.028). On recovery, a category generation task showed no evidence of learning at 0.8 % isoflurane. The aCF

DOES PROPOFOL SUPPLEMENTED ANAESTHESIA AFFECT NEUROPHYSIOLOGICAL OUTCOME FOLLOWING CARDIOPULMONARY BYPASS?

A. S. PHILLIPS*, C. M. McDAID, T. J. McMURRAY AND S. A. LEWIS

Departments of Anaesthetics and Mental Health, The Queen's University of Belfast and the Royal Victoria Hospital, Belfast

Deficit in cognitive functioning has been reported after cardiopulmonary bypass (CPB) which may be greater after valve replacement than after coronary artery bypass grafting (CABG) [1]. It has been suggested that propofol may have cerebral protective properties [2] which could affect neuropsychological outcome. The present study compares the neuropsychological outcome after propofol or isoflurane supplemented fentanyl anaesthesia in patients undergoing valve replacement or CABG.

Forty-one patients undergoing CABG and 20 undergoing valve replacement were included in the study. Patients with neurological dysfunction, evidence of carotid artery disease or long-term benzodiazepine therapy were excluded. Premedication comprised morphine 0.1–0.15 mg kg^{-1}, hyoscine 0.2–0.3 mg and lorazepam 2–3 mg. After induction of anaesthesia with fentanyl 25 μg kg^{-1} patients were allocated randomly to supplementation with propofol 1–10 mg kg^{-1} h^{-1} or 0–2.0 % isoflurane which was continued during CPB. Patients' lungs were ventilated with oxygen-enriched air and additional fentanyl given at sternotomy, start of CPB and rewarming. A constant flow rate was maintained during CPB using a bubble oxygenator and perfusion pressure was maintained

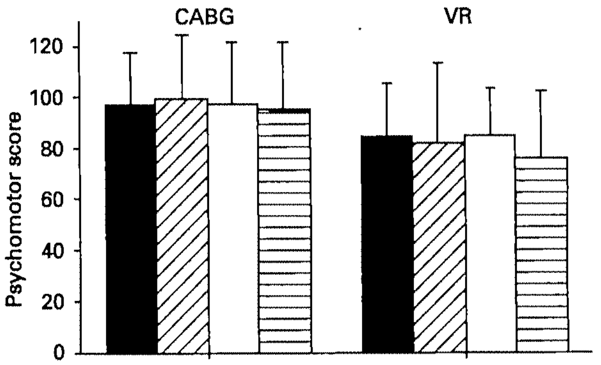

FIG. 7. Mean (SD) psychomotor speed scores in patients undergoing coronary artery bypass grafting (CABG) or valve replacement (VR) before operation in the propofol (■) and isoflurane (□) groups and on day 7 after operation in the propofol (▨) and isoflurane groups (▤).

between 40 and 60 mm Hg and P_{O_2} between 13.3 and 26.7 kPa, using alpha stat criteria. Patients were assessed with a battery of standard psychometric tests before operation and on day 2 and day 7 after operation. These tests measured memory, visiospatial skills, mood and psychomotor speed. Results were compared using analysis of variance.

Analysis of preoperative performance showed that patients undergoing valve replacement had significantly smaller scores in some tests. Performance in all groups was impaired on day 2. However, it had returned to preoperative values by day 7 in most patients as represented by changes in psychomotor speed (fig. 7). The change in performance from baseline to day 2 and day 7 was similar in both CABG and valve replacement patients. There was no significant difference within each surgical group between patients receiving propofol or isoflurane.

HALOTHANE, METABOLITE-INDUCED ANTIBODIES AND HEPATOTOXICITY

J. G. KENNA* AND T. L. KNIGHT*

Department of Pharmacology and Toxicology, St Mary's Hospital Medical School, London

A variety of clinical and laboratory findings suggest strongly that immune reactions play a pathogenic role in the severe form of halothane-induced liver damage, commonly termed "halothane hepatitis" [1, 2]. In particular, previous studies have established that sera from a high proportion of patients with halothane hepatitis contain antibodies to halothane metabolite-modified liver protein antigens, and have implicated this antibody response in the mechanism of liver damage [2]. The metabolite-modified protein antigens comprise a group of at least seven distinct trifluoroacetylated liver microsomal proteins, most of which have been purified and characterized biochemically [2]. Antibodies to the trifluoroacetyl protein antigens have not been detected in a wide variety of control sera, including sera from halothane-exposed patients without evidence of liver damage [2]. It appears that all halothane-exposed individuals produce the antigens, but only a small fraction of susceptible patients mount an immune response and develop hepatitis [2].

Because the antibody response to trifluoroacetyl protein antigens is highly specific for patients with halothane hepatitis, detection of the antibodies is of diagnostic value and we are frequently contacted by physicians who wish us to perform antibody testing. The method we use is an immunoblotting technique, in which liver microsomal fractions from halothane-treated rats are used as the source of test antigen [2]. In the last 2 yr we have been sent serum samples from 12 patients who developed otherwise unexplained liver damage after a recent halothane anaesthetic. We report the results we have obtained.

We received six sera in 1991 from adult British patients. Two patients developed liver failure and underwent liver transplantation; one died. Antibodies to trifluoroacetyl protein antigens were detected in two sera (33 %). In 1992, we received sera from a further six adult patients, four from the U.K., one from Spain and one from the Netherlands. Two of these patients developed encephalopathy and one underwent successful liver transplantation. Antibodies to trifluoroacetyl protein antigens were detected in four of the sera (67 %). Clearly halothane hepatitis continues to be a clinical problem in the U.K. and in Europe.

EFFECT OF FENTANYL ON [^{3}H]NORADRENALINE UPTAKE IN ISOLATED NEURONAL CELL PREPARATIONS

R. ATCHESON, D. J. ROWBOTHAM AND D. G. LAMBERT
University Department of Anaesthesia, Leicester Royal Infirmary

The cellular mechanisms by which opioids produce their clinical effect may include a decrease in neurotransmitter release. In a previous study, we have demonstrated that fentanyl inhibits the evoked release of [^{3}H]noradrenaline from a neuronal cell preparation [1]. Evidence suggests that opioids may also modulate transmitter uptake. Indeed, tramadol, a weak opioid receptor agonist, inhibits uptake of noradrenaline and this may contribute to its analgesic effect [2]. We have utilized two cell lines, a differentiated human neuroblastoma (SH-SY5Y) and a rat phaeochromocytoma (PC12), to examine opioid modulation of noradrenaline uptake.

Cells cultured as a monolayer were incubated with [^{3}H]noradrenaline 40 nmol litre^{-1} in Krebs–HEPES buffer for 1 h, in the absence or presence of fentanyl 0.1–10 μmol litre^{-1}. Excess [^{3}H]noradrenaline was washed from the monolayer and [^{3}H]noradrenaline taken up by the cells was extracted with perchloric acid 0.4 mol litre^{-1}. Data were analysed using Student's paired t test.

TABLE XIII. *Mean* (SEM) *inhibition of* [^{3}H]*noradrenaline uptake by fentanyl in the two cell lines as percentage of the total uptake of* [^{3}H]*noradrenaline in the absence of fentanyl* ($n = 5$–30)

Fentanyl (μmol litre^{-1})	Inhibition (%)	
	PC12	SH-SY5Y
0.1	10.9 (3.0)	3.5 (2.0)
0.3	20.7 (3.2)	17.3 (3.4)
1.0	37.8 (1.7)	26.2 (1.6)
10.0	73.9 (0.9)	58.2 (1.6)

[^{3}H]Noradrenaline uptake was reduced significantly by fentanyl from 0.1 μmol litre^{-1} in PC12 cells ($P < 0.05$) and from 0.3 μmol litre^{-1} in SH-SY5Y cells ($P < 0.05$) (table XIII). Although these concentrations of fentanyl are within the clinical range, it is unclear if this effect plays a significant role in the production of clinical analgesia.

POSTER PRESENTATIONS

EVALUATION OF THE RASCAL II MONITOR

E. PALAYIWA*, E. GRINT*, J. WINYARD*, P. J. FLYNN AND L. STRUNIN
Nuffield Department of Anaesthetics, John Radcliffe Hospital, Oxford and Anaesthetics Units, The London Hospital Medical College, London

The Ohmeda Rascal II monitor utilizes Raman scattering spectroscopy [1] to provide continuous real-time and trend measurement of anaesthetic and respiratory gases. In the monitor, a helium–neon laser interacts with a flowing gas sample that is continuously drawn from the patient breathing circuit. The molecules of each respiratory and anaesthetic gas in the sample give off distinct Raman scattered light with characteristic wavelengths when irradiated by the laser beam. The number of scattered photons for each wavelength is directly proportional to the concentration of a particular gas present. The sensor uses proprietary filters and photon-counting circuits to digitally measure the scattered photon flux at multiple wavelengths. Avalanche photodiodes are used to detect the gas signals which are processed and converted to volume percent gas concentrations. The machine identifies, quantifies and displays inspired and expired concentrations of oxygen, nitrous oxide, nitrogen, carbon dioxide, halothane, enflurane and isoflurane. The monitor can distinguish mixtures of volatile agents. In this latter case the agents are identified and displayed separately.

The accuracy and response times of the Raman spectrometer were evaluated in a laboratory study and the results obtained (table XIV) compared with similar studies of the Datex Capnomac [2] and the Brüel and Kjær monitor 1304 [3]. The responses of the Rascal II were found to be within the manufacturer's specifications for oxygen, nitrous oxide, nitrogen, carbon dioxide and halothane. It was less accurate for large concentrations of enflurane and isoflurane. It was unaffected by water vapour. In the clinical setting the machine was used during semi-open and closed circuit anaesthesia. All clinicians commented on its ease of operation and clear displays.

The Rascal II monitor is a multigas analyser which includes measurement of nitrogen and specific identification of anaesthetic vapours. Comparison with the Datex Capnomac and the Brüel and Kjær monitor was favourable in the clinical range.

HALOTHANE ENHANCES FORSKOLIN STIMULATED CYCLIC ADENOSINE-3′,5′-MONOPHOSPHATE FORMATION IN HUMAN NEUROBLASTOMA CELLS

R. A. HIRST AND D. G. LAMBERT
Department of Anaesthesia, University of Leicester, Leicester Royal Infirmary

As part of a broader programme of research examining the effects of anaesthetic agents on neuronal signal transduction, we have examined the effects of the volatile anaesthetic agent halothane on cyclic adenosine-3′,5′-monophosphate (cAMP) generation in a simple homogenous neuronal cell line of human origin (SH-SY5Y).

cAMP was measured in suspensions of intact cells. The incubation cocktail (300 μl) contained the phosphodiesterase inhibitor, 3-isobutyl-1-methyl xanthine 1 mmol $litre^{-1}$, in the presence or absence of forskolin 10 μmol $litre^{-1}$ to directly activate adenylate cyclase. Reactions were terminated and cAMP extracted as described previously [1]. Halothane was delivered to the reaction using a calibrated Fluotec 3 vaporizer set at 1 % with humidified air as the carrier gas. For control incubations, air alone was used. Data were analysed using the unpaired Student's *t* test.

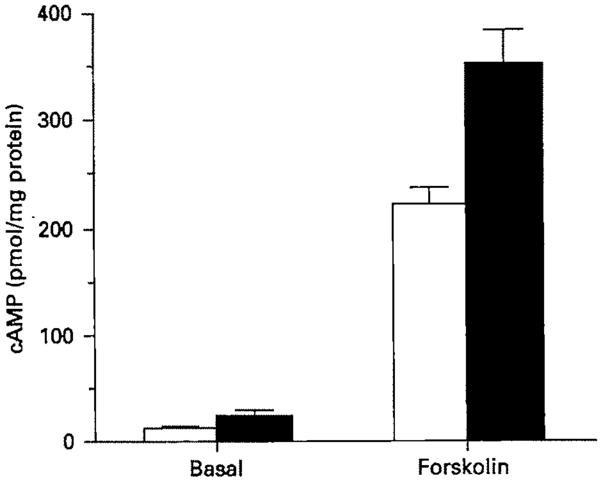

FIG. 8. Effect of halothane (■) on basal (30 min, no forskolin) and forskolin-stimulated (15 min preincubation + 15 min forskolin) cAMP formation. For control incubations, air (□) alone was used.

Halothane at a concentration of 1 % caused significant ($P <$ 0.005) potentiation (60 %) of forskolin-stimulated cAMP formation (fig. 8). The mechanisms underlying this potentiation are currently under investigation and could relate to changes in membrane fluidity at the lipid protein interface or perhaps the effect is secondary to increased intracellular calcium.

PREOXYGENATION AND Sp_{O_2} AFTER INDUCTION OF ANAESTHESIA WITH PROPOFOL AND FENTANYL

D. B. RITTOO*, N. BREED* AND B. J. POLLARD
Departments of Anaesthesia, Hope Hospital, Salford, Royal Lancaster Infirmary, Lancaster and University Department of Anaesthesia, Manchester Royal Infirmary

The introduction of pulse oximeters has increased awareness of arterial desaturation after induction of anaesthesia. We studied prospectively the course of pulse oximeter oxygen saturation (Sp_{O_2}) after induction of anaesthesia with fentanyl and propofol in 29 ASA I patients in whom a laryngeal mask airway (LMA) was inserted.

Patients were allocated randomly into three groups. None of the patients was obese or had any contraindications to the use of propofol, fentanyl or LMA, and there was no history of smoking, chronic respiratory disease, recent chest infection or nasal obstruction. On arrival in the anaesthetic room, arterial pressures were measured and ECG and pulse oximetry monitoring was established. The Ohmeda BIOX 3700e pulse oximeter, set in the fast response mode (3-s update) with finger probe, was used. All patients were unpremedicated and received fentanyl 100 μg i.v. through a 20-gauge cannula in the dorsum of the hand followed by a sleep dose of propofol (3 mg kg^{-1}) over 10–20 s. The LMA (size 3 for females and 4 for males) was inserted at the earliest opportunity. The LMA was connected to a Bain circuit delivering 66 % nitrous oxide in oxygen and 1 % isoflurane. Two gentle positive pressure breaths were administered to verify LMA placement. Ventilation was supported with the preset gas mixture if Sp_{O_2} decreased to less than 90 %.

Group A ($n = 9$; age 21–47 yr; weight 50–80 kg) received no preoxygenation; group B ($n = 10$; age 17–46 yr; weight 50–80 kg) received oxygen 7 litre min^{-1} through a Uno-Plast, 10-French gauge nasal cannula with foam collar in one nostril for 3 min before induction of anaesthesia. These patients were free to talk and nose or mouth breathe during this period; group C ($n = 10$; age 19–37 yr; weight 52–75 kg) breathed oxygen at 8 litre min^{-1} from a face mask on a Bain circuit first flushed with oxygen. The face mask was applied by the operating department assistant at the start of injection of propofol and the patient asked to breathe normally while falling asleep. Sp_{O_2} was recorded every 10 s for up to 230 s. "Tolerated apnoea time", defined as time to return of spontaneous visible ventilatory reservoir bag movements or to application of controlled ventilation, was recorded.

Mean tolerated apnoea time in groups A, B and C were 55, 215 and 200 s, respectively. All patients in group A (no preoxygenation) had Sp_{O_2} values less than 90 %, 60 s after induction. All patients in group B (nasal cannula) maintained large Sp_{O_2} values during the period 0–230 s (range 96–100 %). Two patients in group C (face mask) had Sp_{O_2} values less than 90 % at 120 and 140 s, respectively. In both cases the initial dose of propofol was found to be inadequate and LMA insertion was prolonged. The Sp_{O_2} values of the remaining patients were 95–100 % for the period 0–230 s.

Preoxygenation by nasal cannula for 3 min or by face mask during induction eliminates the incidence of early desaturation associated with propofol and fentanyl induction.

CARDIOVASCULAR EFFECTS OF A PANCURONIUM–VECURONIUM MIXTURE

M. DOYLE*, D. MANNION*, D. McCOY*,
M. O'REGAN*, C. COONEY AND G. FITZPATRICK
Department of Anaesthesia and Critical Care, Meath Hospital, Dublin

Although vecuronium appears to be free of intrinsic cardiovascular effects [1], there have been reports of bradycardia during its use. Pancuronium can be associated with increases in heart rate (HR) and mean arterial pressure (MAP) [2]. We investigated the cardiovascular effects of a pancuronium–vecuronium mixture.

Ethics Committee approval and informed consent were obtained from 73 patients undergoing varicose vein surgery. Patients were allocated randomly to receive either pancuronium (group A, $n = 25$), vecuronium (group B, $n = 23$), or a combination of pancuronium and vecuronium (group C, $n = 25$). The neuromuscular blockers were prepared in a 5-ml syringe as follows: group A, pancuronium 8 mg in 4 ml; group B, vecuronium 8 mg in 4 ml; group C, pancuronium 4 mg plus vecuronium 4 mg in 4 ml. The anaesthetist was unaware of which drug was being used. After premedication with diazepam, anaesthesia was induced with fentanyl 2 μg kg^{-1}, droperidol 0.5 mg, thiopentone 3–5 mg kg^{-1} and 0.05 ml kg^{-1} of neuromuscular blocker. Anaesthesia was maintained with nitrous oxide in oxygen and enflurane. The trachea was intubated and the lungs ventilated mechanically. A 1-ml top-up of neuromuscular blocker was administered on recovery of two responses to a train-of-four stimulation. HR and MAP were recorded before induction, at 1-min intervals for 4 min after induction, at 1-min intervals for 5 min after intubation, before top-up and at 1-min intervals for 3 min after top-up. Significant changes in HR and MAP (±20 %) during anaesthesia were recorded.

There were no significant differences in HR or MAP between patients receiving pancuronium alone and those receiving the

TABLE XV. *Incidence of significant changes in heart rate (HR) in the three groups.* ** P < 0.01

Group	⩾ 20 % Increase in HR at intubation		⩾ 20 % Decrease in HR at any stage		HR < 50 beat min⁻¹	
	No.	%	No.	%	No.	%
Pancuronium ($n = 25$)	17	68	1	4	0	
Vecuronium ($n = 23$)	8**	32	21**	91	8**	35
Pancuronium + vecuronium ($n = 25$)	21	84	3	12	0	

combination mixture. The vecuronium group had a lower HR after induction and intubation than the other two groups ($P < 0.01$, ANOVA). After induction, MAP in the vecuronium group was less than that in the combination group ($P < 0.05$). The frequency of bradycardia (HR < 50 beat min^{-1}) was greater in patients receiving vecuronium alone ($P < 0.01$, Fisher exact test) (table XV). Bradycardia was precipitated by skin incision in two patients and by vein stripping in five patients.

This study suggests that a combination of pancuronium and vecuronium has no clinical advantage in terms of cardiovascular effects compared with pancuronium alone. While vecuronium was associated with a lower HR after induction and intubation it was also associated with a higher incidence of bradycardia.

PHARMACOKINETICS OF THE ISOMERS OF MIVACURIUM CHLORIDE IN THE HEALTHY ADULT

A. G. HEAD-RAPSON, J. C. DEVLIN, G. G. LOVELL*, C. J. R. PARKER AND J. M. HUNTER

University Department of Anaesthesia, Royal Liverpool Hospital and Wellcome Research Laboratories, Beckenham

A solution of mivacurium chloride contains three non-interchangeable stereoisomers: *trans-trans* (57 %), *cis-trans* (37 %) and *cis-cis* (6 %). The aim of this study was to determine the pharmacokinetic parameters of each isomer in healthy subjects.

Five patients weighing between 67 and 85 kg and undergoing intermediate surgery were studied. As mivacurium is known to be metabolized by plasma cholinesterase, the activity of this enzyme was measured before operation [1]. After premedication with oral diazepam 10 mg, anaesthesia was induced with fentanyl 1 μg kg^{-1} and thiopentone 3–5 mg kg^{-1} and maintained with 0.5 % isoflurane (end-tidal) and 70 % nitrous oxide in oxygen. An i.v. cannula for infusion of mivacurium chloride was inserted in one forearm and a 14-gauge cannula placed in the contralateral arm for blood sampling. After a baseline blood sample had been obtained, mivacurium chloride 15 μg kg^{-1} min^{-1} was infused over 10 min using an Ohmeda 9000 infusion pump. The pharmacodynamic response to the neuromuscular blocking agent was measured electromyographically throughout anaesthesia. Blood samples (7 ml) were obtained at 1, 2, 4, 6, 8, 10, 11, 12, 14, 16, 19, 22, 25, 30, 40, 70, 100, 130 and 190 min after starting the infusion of mivacurium and placed immediately into lithium–heparin bottles containing phospholine iodide 5 mg to inhibit plasma cholinesterase. After separation, the plasma samples were frozen until analysis. Mivacurium was extracted from the plasma using a solid-phase technique. The isomers were separated using high performance liquid chromatography and assayed fluorometrically. Mean residence time (MRT), clearance (*Cl*) and volume of distribution (V^{ss}) were calculated for each isomer using non-compartmental analysis [2].

Three males and two females aged between 31 and 58 yr were studied. The range of cholinesterase activity was 890–1280 u litre^{-1} (normal range 620–1370 u litre^{-1}). Mean (range) pharmacokinetic parameters are shown in table XVI. Clearance of the *cis-trans* and *trans-trans*, but not the *cis-cis* isomer, was found to correlate significantly with plasma cholinesterase activity ($r = 0.991$, $P < 0.01$, for both isomers).

TABLE XVI. *Mean (range) pharmacokinetic variables for the three mivacurium isomers*

	Mivacurium isomer		
	trans-trans	*cis-trans*	*cis-cis*
MRT (min)	2.9 (1.7–4.0)	2.1 (0.8–2.8)	42.3 (31.4–56.3)
Cl (ml kg^{-1} min^{-1})	70 (31–94)	138 (52–204)	5.7 (3.7–7.1)
V^{ss} (ml kg^{-1})	185 (123–268)	273 (129–452)	236 (182–341)

The *cis-trans* isomer has the greatest clearance, being twice as rapid as the *trans-trans* isomer. The *cis-cis* isomer has a much lower clearance and longer MRT than the other two isomers. The clearance of the two short acting isomers appears to correlate with plasma cholinesterase activity.

ACKNOWLEDGEMENT

This study was supported in part by a grant from Wellcome Foundation plc.

ASYMMETRY OF UPTAKE AND WASHOUT OF INERT GASES—LESSONS LEARNT IN AN ANAESTHETIC DEPARTMENT

V. FLOOK

Department of Biomedical Sciences, University of Aberdeen

It has always been assumed that the observed asymmetry between uptake and washout of inert gas during decompression is a result of bubble formation [1]. The partition coefficients of inert gases used in diving are very much less than 1.0 in all body tissues. This means that once formed, the gas phase represents a large sink for the dissolved gas and could decrease significantly the partial pressure of inert gas in the surrounding tissue, thereby reducing the driving pressure for gas to move into the blood. In addition, large numbers of vascular bubbles in capillaries may reduce or prevent blood flow, thereby slowing the removal of gas from affected areas.

In fact the asymmetry can be a consequence of the exponential nature of gas dynamics. Figure 9 shows that in fast tissues (i.e. those with short time constants) which reach saturation before the decompression starts, uptake and washout are indeed symmetrical. Compartments with long time constants compared with the time at depth, begin the decompression before reaching saturation, and in these compartments washout is considerably prolonged (fig. 9).

This is a result of the greatly reduced partial pressure gradient between tissue and incoming blood in these slow tissues. Previously published work which has used asymmetry as an

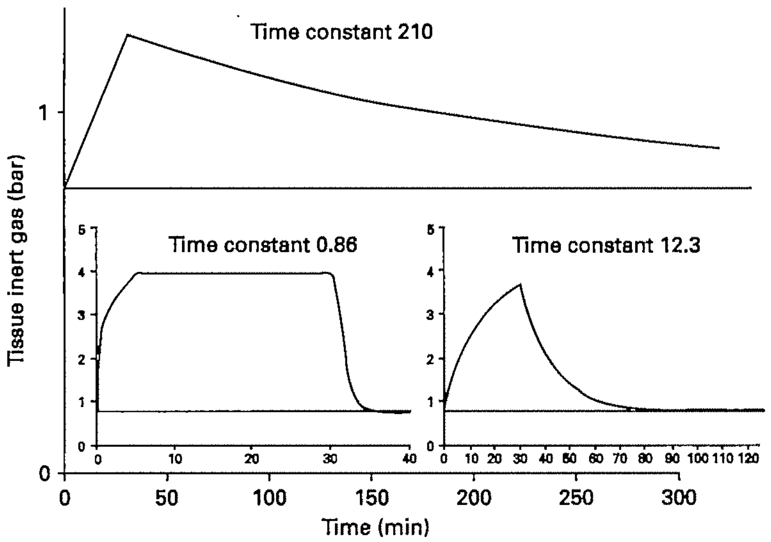

FIG. 9. Gas uptake and elimination for a slow compartment (time constant 210) and for two fast compartments (inserts) for a 2-min decompression after 30 min at 40 m.

indirect indication of the presence of bubbles must be reassessed and the early results from such a reassessment will be presented.

ROUTINE PREOXYGENATION: HOW LONG BEFORE MASK ANAESTHESIA?

A. G. HEAD-RAPSON AND S. L. SNOWDON
University Department of Anaesthesia, Royal Liverpool University Hospital

Arterial desaturation has been shown to be a common event during routine induction of mask anaesthesia, but in the U.K., preoxygenation is not always performed routinely, one reason given for this is lack of time. A more rapid means of preoxygenation, by three large breaths, has been advocated [1] but doubts have been cast on its efficacy [2]. Therefore, we decided to assess the efficacy of preoxygenation performed for only brief durations.

Four methods of preoxygenation were assessed using a Mapleson A breathing system: formal 2 min preoxygenation (oxygen 8 litre min^{-1}), three large breaths (oxygen 8 litre min^{-1}), three large breaths (oxygen 34 litre min^{-1}), one large breath (oxygen 34 litre min^{-1}). In a preliminary study of three healthy volunteers, the end-tidal oxygen achieved by the four different methods of preoxygenation was measured on a breath-by-breath basis using a mass spectrometer (Medishield MS2). Further studies of the effectiveness of each method were performed using a rebreathing system, with continuous monitoring of end-tidal oxygen using the mass spectrometer and of oxygen saturation using a pulse oximeter (Novametrix 500); the rate of desaturation could then be timed.

In one volunteer, the rebreathing bag consistently became empty before desaturation had occurred, except when not preoxygenated and this led us to consider the mechanisms of desaturation at the end of preoxygenation (table XVII).

TABLE XVII. *End-tidal oxygen concentration* (E'_{O_2}) *and time to* Sp_{O_2} *value of 90% during four methods of preoxygenation*

	E'_{O_2} achieved (%)	Time to Sp_{O_2} 90% (min)	E'_{O_2} final (%)
No preoxygenation	15	1.75	7
2 min (8 litre min^{-1})	80	9	7
3 breaths (8 litre min^{-1})	33	Bag empty at 5.25 min	8.5
3 breaths (34 litre min^{-1})	59	Bag empty at 6.9 min	38
1 breath (34 litre min^{-1})	44	Bag empty at 9.5 min	7

In the patient with an obstructed airway, uptake of oxygen volume is not balanced by a return of an equal volume of carbon dioxide, since 90% of carbon dioxide is stored in the body. Oxygen uptake is then associated with a decrease in lung volume until residual volume is reached. At this point, further reduction in volume may increase the shunt and cause gross changes in Sp_{O_2}. As long as the percentage of oxygen is greater than 7% (the level at which $Sp_{O_2} = 90\%$) at this limiting volume, adequate preoxygenation will have been achieved. With this assumption, the end-tidal oxygen concentration that needs to be reached to give adequate preoxygenation can be calculated given oxygen uptake and the residual volume. Three large breaths of oxygen (34 litre min^{-1}) would seem likely to achieve this level of end-tidal oxygen concentration for a large range of values of $\dot{V}O_2$ and residual volume.

CORRESPONDENCE

LUMBOVERTEBRAL SYNDROME AFTER EXTRADURAL BLOOD PATCH

Sir,—I read with interest the case report of Seeberger and Urwyler [1] describing severe back pain after extradural blood patch (EBP). I recently managed a patient with an almost identical problem, and I dispute the authors' conclusions that "this complication ... does not place into question the value of therapeutic EBP".

Whilst relief of headache after EBP is indeed dramatic for many patients, the findings of a large survey of inadvertent dural punctures occurring over a 20-yr period at Birmingham Maternity Hospital [2] are not as encouraging as earlier reports—EBP successfully relieved headache in only 69% of 135 patients (including seven cases requiring repeat blood patch). The same survey revealed that it is unusual for post-dural puncture headache to last for more than 10 days. In common with the patient described in the case report, my patient suffered immobilizing back pain. She was readmitted to hospital 6 days after the procedure and underwent invasive investigation to exclude extradural abscess. Clearly, the value of EBP *must* be questioned if it can result in greater pain and distress than the condition it is intended to treat. (Incidentally, immobilizing back pain after EBP was first described by Cornwall and Dolan [3].)

The authors state that "severe backache after extradural block should be attributed to an extradural abscess or other serious pathological process until proved otherwise". In fact, the evidence confirms that severe backache may follow EBP *in the complete absence* of any demonstrable pathological process. Such was also the case in the patient I managed.

Two of the cardinal features of extradural abscess—pyrexia and leucocytosis [4]—were absent in the patient described and it is debatable if urgent investigation was indicated. Where there is strong suspicion of an extradural abscess, invasive radiological investigation is clearly undesirable and may be avoided if MRI scanning facilities are available.

4. Hulme A, Dott NM. Spinal epidural abscess. *British Medical Journal* 1954; **1**: 64–68.

Sir,—We appreciate the interest of Dr Stride in our recent case report [1] and we share his opinion that the extradural blood patch (EBP) has some potentially serious side effects. We further agree with him that when extradural abscess is suspected, invasive radiological investigation is undesirable unless computed tomography has shown no pathological findings, as in our patient. We look forward to reading his review of experience with EBP at the Birmingham Maternity Hospital, as the surprisingly low success rate contrasts not only with our own limited experience, but also with several reports published on this topic [2–8].

However, we disagree with Dr Stride's conclusion that the value of an effective therapy introduced 31 years ago [9] and in widespread use today [10] must be questioned after three reports of painful side effects (fortunately, none of them with permanent damage). We agree that most patients with post-dural puncture headache (PDPH) do not need an EBP, but this therapy should be offered to the small percentage of patients with severe PDPH not responding to conservative treatment. Moreover, the syndrome of continued leakage of CSF after dural puncture may be complicated in rare cases by cranial nerve palsies [11], and even fatal subdural haematoma [12].

The most important point of disagreement, however, results from Dr Stride's statement that "it is debatable if urgent investigation was indicated". Many publications confirm that the extent of permanent neurological sequelae is related directly to the time required for diagnosis and surgical correction of haematomas [13–17] or abscesses [18, 19] associated with lumbar punctures. Indeed, Saady mentioned that an atypical presentation of extradural abscess may be a cause for delayed diagnosis [19]. Therefore, we reaffirm our statement that immediate investigation is warranted in any patient with immobilizing back pain after lumbar puncture.

INTERMITTENT *VS* CONTINUOUS EXTRADURAL INFUSION OF BUPIVACAINE DURING LABOUR

Sir,—The absolute significance of the findings of Eddleston and colleagues [1] would have been much clearer if they had compared the two extradural groups with a control group which did not receive extradural bupivacaine. Although this control group would have been self-selected and not subject to randomization, the group could have been matched as closely as possible to the two study groups.

In addition, although the incidence of oxytocin use was recorded in this study, an analysis of the association between oxytocin use and the fetal heart rate abnormalities would have provided additional information. This association is recognized widely, and ascribing heart rate abnormalities to different extradural techniques irrespective of the use of oxytocin may not be valid.

Whilst it is tempting to attribute fetal heart rate abnormalities to uptake of bupivacaine by the fetal myocardium, the evidence for this is far from conclusive. Although Abboud and colleagues [2] also observed fetal heart rate abnormalities after extradural bupivacaine, other factors may have been contributory. In the large majority of cases, abnormalities are associated with aorto-caval compression which is not always diagnosed or recognized [3]. The umbilical vein:maternal vein concentration ratio of bupivacaine is only an index of placental transfer in that it describes the equilibrium concentration ratio of bupivacaine across the placenta at one moment in time. Although Kuhnert and colleagues [4] suggested that low fetal: material ratios were caused by extensive fetal tissue uptake, more recent work in animals by Laishley, Carson and Reynolds [5] does not support this. In our study, in the presence of a constant maternal arterial concentration of bupivacaine, fetal plasma and brain concentrations increased slowly over 120 min and only approached a fetal:maternal ratio of 0.3 at that time. Moreover, despite bupivacaine being lipophilic, the fetal brain:fetal blood concentration ratio diminished over this time. This latter finding indicates that there is not extensive tissue uptake by fetal brain.

The predominant reason for the low fetal:maternal ratio of bupivacaine is the difference in concentration in alpha$_1$-acid glycoprotein across the placenta, and the resulting relative difference in the proportion of bupivacaine bound to glycoprotein [6]. Moreover, fetal acidosis, which may be associated with the use of oxytocin, promotes placental transfer of bupivacaine by ion trapping of the basic drug [7]. The study by Reynolds and colleagues [8] confirmed the relatively small fetal plasma concentration of bupivacaine (umbilical samples at delivery) after a large bolus dose of extradural bupivacaine for Caesarean section. If it is hypothesized that bupivacaine causes fetal myocardial toxicity in these small concentrations, then it suggests that the fetal myocardium is much more sensitive than adult myocardium.

Finally, the conclusion of Eddleston and colleagues [1] that there is no advantage in either extradural intermittent bolus or infusion techniques ignores the fact that the infusion technique may be safer. A survey of the Reports on Confidential Enquiries into Maternal Deaths between 1970 and 1987 [9] reveals that four of the 10 deaths directly associated with extradural analgesia were caused by total spinal anaesthesia and extradural bolus doses of bupivacaine. So far, there are no descriptions in these reports [9] of any death associated with an extradural infusion.

Sir,—Thank you for the opportunity of replying to Dr Laishley's detailed letter. Our study was an attempt to examine, in particular, the potential effects on the fetus of extradural analgesia with bupivacaine. Exhaustive studies comparing intermittent and continuous infusion extradural analgesia with bupivacaine failed to demonstrate any maternal advantage associated with either regimen [1, 2]. To date, no attention has been paid to the effect of the two regimens on the fetus, in particular fetal heart rate pattern. In our study, we documented 71 deceleratory episodes in the intermittent group and 69 in the infusion group. We found no difference between groups in the incidence of deceleration occurring within 30 min of an extradural top-up, but we did detect a discrepancy in its severity and duration. In the intermittent group, the majority of decelerations (73.8%) were recorded as transient, whereas in the infusion group 61.1% of episodes lasted in excess of 10 min.

Indeed, there are several other potential causes for fetal heart rate decelerations, including aortocaval compression producing hypotension, the use of oxytocics and fetal acidosis, all of which are referred to in Dr Laishley's letter. I can restate that none of the deceleratory episodes referred to in our paper occurred in the presence of maternal upper limb hypotension. Obviously, this does not exclude the presence of concealed aortocaval compression. In addition, there was no difference in the mean dose of oxytocic required by each treatment group or in the acid–base status of the two groups at delivery.

Finally, we accept Dr Laishley's comments concerning a control group. Such a group almost universally would have received another form of analgesia, most probably parenteral pethidine. We do not feel that this could be described as a control group.

In conclusion, we wish to restate that there is no advantage to either mother or fetus in using an extradural infusion of 0.125% bupivacaine compared with intermittent injections of 0.25% bupivacaine. We accept, however, that the infusion technique should, in theory, be less likely to produce total spinal anaesthesia in the case of a misplaced extradural catheter.

DOES ETOMIDATE CAUSE HAEMOLYSIS?

Sir,—I read with interest the article "Does etomidate cause haemolysis?" by Nebauer and colleagues [1], as it reminded me of an unreported finding after etomidate use in domestic cats. We conducted research several years ago at the Veterinary Teaching Hospital at the University of Illinois to determine the anaesthetic effects and pharmacokinetics of etomidate in domestic cats [2, 3]. We used Amidate i.v. (Abbott Laboratories) in a dose of 3 mg kg^{-1}

(this dose is 10 times greater than the dose reportedly used in man). In our study, multiple samples of venous blood were obtained from each cat for analysis of the plasma concentration of etomidate (2.5 min to 12 h). All blood samples were haemolysed. This did not interfere with the analyses, but was of interest. I am sure that the haemolysis was more obvious to us because of the greater dose used.

As was mentioned in the article, etomidate is prepared with a propylene glycol base (35 vol %). It has been reported previously that propylene glycol does indeed cause haemolysis [4]. Thus haemolysis occurring in man is most likely to be produced by the vehicle.

4. Gross DR, Kitzman JV, Adams HR. Cardiovascular effects of intravenous administration of propylene glycol and of oxytetracycline in propylene glycol in calves. *American Journal of Veterinary Research* 1979; **40**: 783–791.

Sir,—We read with interest the letter of Dr Wertz reporting haemolysis in cats after the use of etomidate dissolved in propylene glycol (PG). In reviewing the literature we had also found a report on PG-induced Heinz body formation, change in membrane deformability, reduced erythrocyte survival and haemolysis in cats fed with PG-containing pet food. Also, *in vitro* tests caused haemolysis of red blood cells [1].

We decided not to refer to these observations in our article because feline erythrocytes differ from human red blood cells and appear to be more susceptible to damage. However, we do now wish to refer to an article by Molter and colleagues [2], who reported haemolysis, *in vitro* and *in vivo*, using etomidate dissolved in 45 vol % PG.

Whether haemolysis is caused by hyperosmolality of the solution, by a direct effect of PG on cell membranes, or both, has to be investigated further. In conclusion, all authors have suggested re-evaluation of the safety of propylene glycol, especially in large concentrations and when administered over a prolonged time.

XYLOMETAZOLINE AND PORPHYRIA

Sir,—A 45-yr-old female who had variegate porphyria diagnosed in 1979 presented for submucous resection of the nose. Several previous anaesthetics had made her feel unwell. Symptoms included blistering of the skin, depression and abdominal and joint pain. She was prescribed β carotene.

She did not receive any premedication. Anaesthesia was induced and maintained with propofol (total dose 300 mg), fentanyl 0.05 mg and 60 % nitrous oxide in oxygen, administered via a laryngeal mask and a Bain coaxial circuit. An adrenaline nasal pack inserted in the ward was removed before surgery and local anaesthesia was not used. Anaesthesia and recovery were uneventful.

Urine samples collected for 24 h before, and 24 h and 48 h after operation were screened for porphyrins (table I).

TABLE I. *Urinary porphyrin concentrations*

	Porphobilinogen (μmol/24 h)	Total porphyrin (nmol/24 h)
Reference values	0–12	0–320
Before anaesthesia	6.39	215
After anaesthesia		
24 h	7.80	430
48 h	19.86	475

The results revealed normal concentrations of porphyrins before operation. Xylometazoline (Otrivine) nasal spray was used 20 h after operation and was the only drug associated with the increase in porphobilinogen concentration. Xylometazoline has been advocated as a safe alternative to other vasoconstrictors and is used commonly in nasal surgery. It may be advisable to avoid its use in porphyric patients.

TRANSTHORACIC ENDOSCOPIC SYMPATHECTOMY

Sir,—We read with interest the recent article on transthoracic endoscopic sympathectomy for upper limb hyperhidrosis [1]. We have used this technique in three patients and agree with the observation that postoperative pain is mainly retrosternal, but in our patients this lasted for more than 12 h. We postulate that this was the result of manipulation and displacement of the mediastinum during carbon dioxide insufflation and subsequent one-lung anaesthesia. There was minimal discomfort from the puncture sites. We have provided analgesia via intrapleural catheters in all our patients, two of whom had bilateral procedures.

The catheters were introduced by the surgeon under direct vision through one of the endoscopy ports before reinflation of the lung. The catheter was placed at the apex of the lung in the vicinity of the operation site. Postoperative analgesia was achieved in all our patients with 0.25 % bupivacaine 20 ml, given via one or both catheters in recovery, and repeated 4 and 12 h later. A second advantage of intrapleural catheters has been the ability to extract any residual pneumothorax.

Our experience includes bilateral procedures and sequential lung collapse. We have noted periods of arterial desaturation during one-lung anaesthesia on the second side. We feel that there is a significant period of time after reinflation of the first lung when pulmonary physiology is inadequate to sustain oxygenation on that lung.

Sir,—We thank Drs Gilligan, Smith and Allen for their comments on our recent article [1].

Nearly all our patients experienced pain during the first 4 h after surgery, unless there was any complication (pneumothorax, haemothorax or the need for a thoracic drain). This retrosternal or upper back pain was controlled with a combination of preoperative midazolam and fentanyl, with an additional postoperative i.v. or i.m. dose of opioid titrated to the individual patient's needs. We were reluctant to use intrapleural analgesia administered via a catheter inserted through the endoscope because of the possible danger of bilateral phrenic nerve block [2].

It is unnecessary to leave a catheter in the pleural cavity to treat a residual pneumothorax, as this can be avoided by reinflating the lungs under direct vision until they are seen to bulge into the lumen of the endoscope. We are of the opinion that such a catheter would complicate the procedure and increase the duration of stay in hospital. Patients lacking complications were discharged from hospital after 12–24 h.

We did not compare the incidence of arterial desaturation between the first and second side. We discussed in our article the possible mechanism of this desaturation. In practice, after it had been checked that there was no endobronchial tube misplacement, the arterial desaturation immediately improved with one or two small manual ventilations of the collapsed lung. This manoeuvre does not disturb the surgeon and we would suggest that the arterial desaturation is related to the degree of lung collapse [3].

3. Marshall BE, Marshall C. Continuity of response to hypoxic pulmonary vasoconstriction. *Journal of Applied Physiology* 1980; **49**: 189–196.

Sir,—We read with interest the article by Jedeikin and colleagues on anaesthesia for transthoracic sympathectomy as treatment for upper limb hyperhidrosis [1, 2]. They reported that 56 of their 58 patients experienced distressing retrosternal or upper back pain during the first 2–4 h after operation. Recently, we have anaesthetized six patients for this procedure in our hospital and have found that intrapleural 0.5% bupivacaine introduced immediately before removal of the last endoscopic port provided excellent postoperative pain relief. As far as we are aware, this technique has not been described previously [3–6].

Whereas 43 of Dr Jedeikin's 58 patients had bilateral sympathectomies, all of our patients had unilateral procedures. In most respects, the anaesthetic techniques were similar. Our patients received either no premedication or a benzodiazepine. Induction was with thiopentone 3–5 mg kg^{-1}. Intubation and intermittent positive pressure ventilation were facilitated with vecuronium 0.1 mg kg^{-1}. All patients had the trachea intubated with left-sided Robertshaw endobronchial tubes and anaesthesia was maintained with enflurane in oxygen–nitrous oxide supplemented with either papaveretum 0.2 mg kg^{-1} or alfentanil 0.1 mg kg^{-1}. At the end of the procedure, 0.5% bupivacaine 2 mg kg^{-1} was instilled intrapleurally. No intrapleural drains were left *in situ*.

All patients were comfortable in the recovery ward, the worst pain being described as a dull ache in the ipsilateral arm and relieved by paracetamol. No toxic effects of bupivacaine were seen [7] and all patients were discharged from hospital within 24 h.

From our limited experience, it would seem that this technique provides effective pain relief for the procedure of transthoracic endoscopic sympathectomy.

PERIOPERATIVE BLOOD LOSS

Sir,—The review by Dr Simpson on perioperative blood loss and its reduction was most interesting [1]. As the level of concern about transfusion-related infection has increased greatly in the past decade, so has interest in means of reducing requirements for blood products. The other reason for reducing intraoperative bleeding is to facilitate surgery by providing a bloodless field. However, the article did not include some of the most recent techniques available to the anaesthetist to decrease blood loss.

Normovolaemic haemodilution is used often to decrease the need for transfusion of homologous blood. The technique is safe and effective as long as rigorous criteria are followed [2]. The technique also offers several advantages such as increased cardiac output, better regional blood flow and better tissue perfusion. The practical aspects, physiological consequences and inclusion criteria of the technique have been reviewed recently [3].

Specific pharmacological agents have been used to decrease blood loss. They are used more commonly during operations in which massive blood loss is anticipated, such as during cardiac surgery and orthotopic liver transplantation. An impressive reduction in both intraoperative and postoperative blood loss was reported after the use of high dose aprotinin during cardiac surgery [4]. Aprotinin (Trasylol) is a serine protease inhibitor known to inhibit human plasmin, trypsin and tissue kallikrein. It is postulated that aprotinin prevents the activation of plasma proteins and platelets during cardiopulmonary bypass, and thereby helps to preserve normal coagulation. Aprotinin has been used successfully for the reduction of blood loss after liver transplantation [5] and peripheral vascular surgery [6]. Synthetic and natural antifibrinolytic agents have been used to decrease bleeding after cardiac surgery.

Desmopressin, a synthetic form of the hormone vasopressin which releases factor VIII and von Willebrand's factor from endogenous sites, has been used to reduce bleeding during major orthopaedic surgery [7] and complicated valvular surgery [8]. Tranexamic acid [9] and ε-aminocaproic acid [10] have been shown to decrease postoperative bleeding after cardiopulmonary bypass. However, the initial reports concerning these agents have not been substantiated and their use during surgery is much debated.

A variety of techniques can aid the anaesthetist in reducing perioperative blood loss, but the clinician must weigh the benefits and disadvantages of these intraoperative techniques in each patient before deciding to use any one.

It should be noted that Dr Simpson's review on perioperative blood loss was commissioned originally as part of a Postgraduate Educational issue, devoted to various aspects of haematology. Some 10–11 articles were commissioned and some of these would have dealt in great detail with the other methods of decreasing blood loss, referred to above by Dr Appadu. Unfortunately, however, most of these reviews failed to materialize and it was not possible to produce a single issue. Thus Dr Simpson's article covered only the area requested of him by the Editor of Educational Reviews.

PRE-EMPTIVE EXTRADURAL ANALGESIA

Sir,—In their letter, Dr Wilder-Smith and colleagues [1] ask an important question which neither they nor the replying letter [2] address. Why do yet further studies fail "to produce the results expected from previous experimental work [3]" in relation to pre-emptive analgesia?

This previous experimental work with the concept of "pre-emptive analgesia" and related concepts such as "wind-up" were derived in neurophysiological laboratories in which stimuli are applied to (often neonatal and often decerebrate) animal spinal cord preparations [4], and responses such as the electrical output of neurones including ventral horn (motor) cells [4] measured. In order to obtain the so-called pre-emptive analgesia in rats "low-dose" morphine (0.5 $mg\ kg^{-1}$) is used, as opposed to larger doses (5 $mg\ kg^{-1}$) needed to suppress this effect when the drug is given after the stimulus [5]. Such industrial doses have no relevance to clinical practice. The phenomenon of wind-up lasts only a few minutes [6] compared with the pain response after injury, which lasts for days. Discussion about the comparative actions of lignocaine or bupivacaine are irrelevant, as there are no comparative studies.

In the clinical studies of extradural analgesia [7, 8] and peripheral neural block [9], the pain report of conscious man is measured after standard surgical insults. The two experimental systems are assessing totally unrelated events—what would be an even greater surprise would be for there to be any correlation between the two, not that there is a lack of correlation. To answer the question as posed, the studies of analgesia in man "fail to reproduce previous experimental work" because that work was not the study of pain or the response of analgesics in man. Pain is not just nociception. It is *only* by the study of pain and pain mechanisms in man that there will be any advances in clinical practice.

METABOLIC EFFECTS OF CHOLECYSTECTOMY

Sir,—We read with interest the study of Joris and colleagues [1] comparing the metabolic and respiratory changes after standard and laparoscopic cholecystectomy. We have compared the same variables after minilaparotomy and laparoscopic cholecystectomy as part of a prospective, randomized controlled trial. In our study, after laparoscopic cholecystectomy there were better postoperative pulmonary function and oxygen saturation, and lower pain scores and morphine consumption using a patient-controlled analgesia device than after a minilaparotomy cholecystectomy [2–4]. In these respects, our findings are in agreement with those of Joris and colleagues.

However, our findings on the metabolic response to surgery after the two procedures (10 patients in each group) [5] differ significantly. Serum C reactive protein (CRP) was measured by nephelometry, while serum interleukin-6 (IL-6) was measured using a hybridoma growth stimulation assay. Values were (means (SEM)): CRP at 48 h—laparoscopy 118 (50) $mg\ litre^{-1}$, minilaparotomy 122 (30) $mg\ litre^{-1}$; IL-6 at 24 h—laparoscopy 227 (41) $pg\ ml^{-1}$, minilaparotomy 252 (46) $pg\ ml^{-1}$.

In our study, there was a wide variation in the metabolic response within groups, but there was no significant difference between the two groups. As a result of a different assay technique, our IL-6 results are substantially greater and cannot be compared directly with those of Joris and colleagues. Furthermore, in our study, the CRP response after laparoscopic cholecystectomy was more than twice that found by Joris and colleagues. Given that there is wide variation in the magnitude of the metabolic response to surgery, it is not surprising that studies with small patient numbers can produce such different results. In the study of Joris and colleagues, patients were not allocated randomly to groups. Patient selection bias may, therefore, account for the difference in findings.

5. McMahon AJ, O'Dwyer PJ, McMillan D, Cruikshank A, Lowe G, Rumley A, O'Reilly D, Logan R, Baxter JN. Does the laparoscopic method result in a reduced metabolic response to surgery? *Irish Journal of Medical Science* 1992; **161** (Suppl. 11): 39.

Sir,—We appreciate the interest of McMahon and colleagues in our work [1] on the metabolic and respiratory changes after standard and laparoscopic cholecystectomy. Using randomized studies, Putensen and colleagues [2] and McMahon and colleagues [3, 4] confirmed better postoperative pulmonary function, greater Sp_{O_2} and smaller pain scores, opioid consumption, or both, after laparoscopic cholecystectomy than after open cholecystectomy as demonstrated in our article.

Laparoscopic cholecystectomy avoids a large abdominal incision and attendant retraction. Furthermore, gall bladder dissection "appears" less traumatic, less extensive and more precise during laparoscopy. The reported benefits of laparoscopy on postoperative pulmonary function and pain were therefore expected and, for us, were related mainly to reduction of surgical trauma. We measured C-reactive protein (CRP) and IL-6 to document objectively the reduction in tissue injury. Increases in plasma concentrations of IL-6 and CRP, considered as indicators of the amount of tissue damage [5, 6] were significantly less after laparoscopy. McMahon and colleagues [7], however, could not find any significant difference between laparoscopic and open cholecystectomy.

We do not think that patient selection bias accounts for the discrepancies between the findings of their randomized study, and ours which was not randomized. First, our study was carried out early after the introduction of laparoscopic cholecystectomy. All the patients in our study were operated on by experienced senior surgeons, more acquainted with the technique of open than laparoscopic cholecystectomy. We suspect, therefore, that the difference reported in our study would be even greater if the comparisons were to be made now, 2 years later. Second, although the study was carried out shortly after the introduction of laparoscopic cholecystectomy, by the time we decided to undertake it, open cholecystectomies were no longer performed in our hospital except for acute cholecystitis or complicated cases. A randomized, controlled study of open *vs* laparoscopic cholecystectomy was not appropriate when our study was designed and, I regret, will no longer be possible in the light of the multiple benefits favouring the laparoscopic approach [8]. We therefore used historical controls [1].

We also noticed a wide within-group variation for CRP (measured by nephelometry), but this was still five times less than that of McMahon and colleagues. Serum concentrations of CRP in their study were very great. The mean concentrations of CRP in our study were in the range reported in other studies [9, 10]. As far as IL-6 is concerned, we used a radioimmunometric assay, whereas McMahon's group used a bioassay; comparison of the two sets of data for IL-6 is therefore difficult. However, Jakeways and colleagues [11], using a bioassay, also reported peak plasma concentrations of IL-6 and CRP significantly greater after laparotomy than after laparoscopy. Moreover, peak plasma concentrations of IL-6 and CRP correlated well in our study. Therefore, as our findings were expected and confirmed clinical observation, we consider our data valid.

British Journal of Anaesthesia 1993; **70**: 17–21

Equation (7) should read: $\mathrm{d}t = \mathrm{d}\theta/2\pi f$

In the equation after equation (8) the right hand side should begin, not $(k\dot{v}/2\pi f)$, but $(k\dot{v}^2/2\pi f)$.

UNIVERSITY OF LEEDS

ACADEMIC UNIT OF ANAESTHESIA

A Revision Course for the Part 3 FRCA Examination

To be held at St. James's University Hospital, Leeds
10th-14th May, 1993 inclusive

This is an intensive five-day course intended for candidates about to enter the Part 3 examination. The course consists of lectures, tutorials and clinical teaching covering those aspects most relevant to the examination. Sessions on examination technique will cover essay writing, MCQs, clinical and oral examinations.

Fee £300.00. (accommodation extra)

Early application is advised as places are limited

For further information and an application form, please contact:

Academic Unit of Anaesthesia
St. James's University Hospital,
Leeds LS9 7TF.

Telephone: 0532 836972

National Guard King Khalid Hospital, Jeddah, Saudi Arabia

International Hospitals Group has provided British management at this prestigious 340 bed hospital, since 1981 and is justly proud of its excellent reputation for high standards. Jeddah is a fascinating cosmopolitan city which combines both Western and Middle Eastern ways of life. Located in the Western province and situated on the Red Sea coast it is also the Kingdom's commercial centre.

Consultant Anaesthetist

£51,720 p.a.Tax Free

The department in our busy modern hospital has a complete and varied surgical, obstetrics, general and intensive care work load which includes major neonatal and paediatric surgery. Candidates will be expected to have held a NHS Consultant post or equivalent following completion of higher professional training.

We offer excellent benefits which include:

★ 49 days Annual Leave ★ Free Flights Every Six Months for Self, Spouse and up to 3 Dependent Children
★ Education Allowance for up to 2 Dependent Children
★ Free Accommodation and Utilities
★ Free Expatriate Financial Advice Service

AIDS AND THE LUNG
EDITED BY DAVID MITCHELL AND ASHLEY WOODCOCK
ARTICLES REPRINTED FROM THORAX
BMJ

"This book is a beauty!

I found it interesting and it answered many questions I had on the respiratory consequences of AIDS—plus many I wouldn't have even thought of. This book has great value for all practitioners (from medical students to specialists) who deal with AIDS and the lung."
The Medical Journal of Australia

In *AIDS and the lung* experts review the problems, emphasising practical points and providing up to date information on this rapidly changing subject. Edited by David Mitchell, consultant physician in respiratory medicine, St Mary's Hospital, London, and Ashley Woodcock, consultant chest physician, Wythenshawe Hospital, Manchester, *AIDS and the lung* is an indispensable handbook for respiratory physicians, especially those with limited experience of dealing with AIDS—and for everyone concerned with protective measures in bronchoscopy units and pulmonary function laboratories.

UK £8.95; Abroad £10.00
BMA members £8.45 or £9.50 including postage, by air abroad

Histaminfreisetzung bei der Einleitung von Kombinationsnarkosen mit Nalbuphin oder Fentanyl *

Modulierung der Reaktion durch die Prämedikation Promethazin/Pethidin

Zusammenfassung

In einer kontrollierten klinischen Studie an 24 allgemeinchirurgischen Patienten wurde die Histaminkonzentration während der Einleitungsphase einer Kombinationsnarkose mit Nalbuphin (1 mg/kg) oder Fentanyl (5 µg/kg) untersucht. Zur Prämedikation erhielten die Patienten Promethazin (Atosil®) und Pethidin (Dolantin®) 30 min vor den Opioiden. Die Narkoseeinleitung erfolgte mit Alcuronium-Flunitrazepam-Thiopental-Succinylcholin. Nach der Intubation wurde die Analgesie mit Nalbuphin oder Fentanyl aufrechterhalten. Nalbuphin und Fentanyl erwiesen sich als Histaminfreisetzer mit einer mehr als 40%igen Inzidenz. Nalbuphin aber modulierte (potenzierte) noch dazu die Histaminfreisetzung durch die Kombination Alcuronium-Flunitrazepam-Thiopental. Dieser Unterschied zwischen Nalbuphin und Fentanyl war statistisch signifikant (Inzidenz 46% gegen 9%!). Eine direkte Korrelation zwischen Histaminfreisetzung und hämodynamischer Instabilität konnte nicht nachgewiesen werden. Auch eine detaillierte Kausalitätsanalyse mit bedingten Wahrscheinlichkeiten und der Annahme einer beitragenden Determinante für Histamin ergab, daß die Histaminfreisetzung die gemessenen hämodynamischen Parameter kaum beeinträchtigt. Eine mögliche Ursache dieser Ergebnisse besteht in der zeitgerechten vorherigen Gabe von Promethazin, das sowohl eine starke H_1-antagonistische Wirkung wie auch eine H_2-antagonistische Wirkung entfaltet.

Histamine release during induction of anaesthesia with nalbuphine or fentanyl. Modulation of the reaction by premedication with promethazine/pethidine

Abstract

In a controlled clinical trial in patients admitted for general surgery (mainly abdominal and thyroid) histamine release following nalbuphine 1 mg/kg i.v. versus fentanyl 5 µg/kg i.v. was studied in the course of an otherwise routine induction with promethazine-pethidine as premedication 30 min before the opioids and alcuronium-flunitrazepam-thiopental 5 min later. Succinylcholine was given before intubation and further analgesia was obtained by repeated administration of either nalbuphine or fentanyl. Plasma histamine levels were measured by a specific fluorometric assay, heart rate and blood pressure were measured for assessing hemodynamics, and clinical signs of anaphylactoid reactions such as skin eruptions and arrhythmias were registered.

Results. Nalbuphine and fentanyl both released histamine with an incidence of more than 40%. In addition, nalbuphine potentiated the histamine release evoked by the sequential administration of alcuronium-flunitrazepam-thiopental in one complex of application. The incidence of histamine release in the nalbuphine group was 6/13 = 46%, in the fentanyl group only 1/11 = 9% (chi² test, $P < 0.05$). Furthermore, this study showed high histamine levels after succinylcholine and intubation in a relation to time of administration that suggested histamine release as a stress response to intubation. Finally the incidence of histamine release after a second injection of the opioids was still 30%. A direct correlation between plasma histamine levels, hemodynamic changes, and skin reactions could not be shown. A detailed causality analysis with histamine release as a contributory determinant showed histamine release less detrimental to hemodynamic stability than the opposite, which had been expected. However, the promethazine administered 30 min before induction of anaesthesia had strong H_1- and H_2-receptor antagonistic activity and was given with optimum timing for H_1- and H_2-prophylaxis.

Conclusion. The study demonstrated that histamine release during anaesthesia and surgery depends strongly on the time sequence of drugs and

BOOK REVIEWS

ABC of Transfusion, 2nd Edn. Edited by M. Contreras. Published (1992) by BMJ Publishing Group, London. Pp. 66; indexed; illustrated. Price £12.95.

The first edition of this paperback was a compilation of 16 articles which appeared in the *British Medical Journal*. After only a 2-year interval a second edition is available. I understand that this is because of the success of the first edition and because of the significant changes in the labelling of blood and blood products which has necessitated the change of all illustrations, in this heavily illustrated work, which feature pack labels. The multi-authorship has acquired an additional name and the format has remained essentially unaltered. Careful comparison of the two editions confirms changes of detail in a majority of chapters to bring the material completely up to date, relating to matters, for example, of pretesting of donations for antibody to hepatitis C virus and HIV 2.

Overall the book is aimed, successfully, at those who use blood but who work in specialties other than transfusion medicine, and this is emphasized by the editor. It contains a great deal of what the trainee anaesthetist, theatre nurse and operating department assistant need to know about blood transfusion from donor to clinical area and much more besides. It should be read by all these groups, as it is admirably succinct (62 pages of text) and perhaps also by some of us who consider ourselves fully trained.

The concluding chapter by the National Director of the Blood Transfusion Service in England and Wales confirms that the U.K. is now self sufficient in blood and blood products—a situation which can only be maintained by intelligent usage, as so carefully set out in the book.

J. K. Wood

British Medical Bulletin: A Series of Expert Reviews. Pain, Mechanisms and Management. Edited by J. C. D. Wells and C. J. Woolf. Published by Churchill Livingstone, Edinburgh. Pp. 791; indexed; illustrated. Price £33.00.

This edition of the quarterly *British Medical Bulletin* is concerned with pain, its mechanisms and management. The editors have assembled a host of well-known clinicians and scientists in order to provide 18 relatively short reviews on nearly every aspect of pain, both acute and chronic. There is no logical format to the book, but the chapters can be divided broadly into those concerned with basic physiology, clinical practice, pharmacology and psychology.

Woolf gives an excellent account of the central generation of acute pain and there are chapters on the chemical activation of nociceptive peripheral neurones, mechanisms of acute visceral pain and peripheral and central mechanisms of neuropathic pain. These purely scientific reviews are probably the best in the book; each chapter is well written, referenced and illustrated.

The clinical reviews are in general very good also, but some suffer from the fact that the authors have been asked to cover very large areas of interest in relatively short articles. Consequently, some of these tend to be rather superficial, but they do provide an excellent start for the reader with little knowledge of the subject. An example of this is the chapter describing the clinical management of acute pain. This is an enormous area and the authors have attempted to be very comprehensive in their treatment of the subject. Consequently, it lacks detail. Other reviews of clinical practice include the management of sympathetic pain, neurogenic pain syndromes and pain in children.

There is a fine review of the clinical pharmacology of opioids in this book and articles concerned with psychological aspects of pain, both genesis and treatment, are well written and balanced.

Who will find this book useful? It is to be recommended for all those sitting the F.R.C.Anaes. Part 3 examination and for those clinicians who are not in the field of pain management but feel that they need a broad picture of present clinical and academic activity in this specialty. It is not for, and I suspect not aimed at, specialists in pain management.

D. Rowbotham

Specialty Medical Audit (Medical Audit Series 4). By C. Shaw. Published by King's Fund Centre, London. Pp. 206; indexed; illustrated. Price £7.50.

It is surprising that such a simple concept as medical audit has created so many different interpretations and methods of application. Every medical specialty has developed audit tailored to its own requirements, so that at the present time medical audit has a myriad of facets which may be difficult to make sense of.

This book gives a snap-shot in time to convey the current state of medical audit in acute hospital services in the U.K. The first half of the book gives a global description of medical audit from its history and national organization to the principles of its practice, common methods of application and the resources required to undertake it. The second half is separated into chapters describing medical audit in each of the major hospital acute specialties.

The section on Anaesthetics and Intensive Care gives a short account of most of the published work on anaesthetic audit and there is a good selection of references. It is disappointing that Intensive Care does not feature very greatly, although this probably reflects the volume that has been written on this subject. Subjects covered include national guidance from the College, a brief description of difficulties encountered in organizing departmental audit and various auditing methods, from topic review to the use of key indicators and adverse patient events. CEPOD is described, and methods of data collection are discussed. Critical incident reporting is barely mentioned, as is the interface with risk management. It is interesting to make comparisons of audit across specialties, and in this context, most specialities involve sampling of notes and cases, which does not seem to feature in anaesthetic audit.

In summary, this small book acts as a good practical manual of audit methods for those involved in hospital audits and gives an overview of the framework that has been created nationally for medical audit.

A. G. H. Cole

Management of Acute Pain: A Practical Guide. Edited by L. B. Ready, W. T. Edwards and the Task Force on Acute Pain. Published by IASP Publications, Seattle. Pp. 73; indexed; illustrated. Price $15.

This handbook is the first product of the International Association for the Study of Pain Task Force on Acute Pain. The Task Force, chaired by Dr L. Brian Ready, is mainly American, with some representation from Europe and Australia. This is a slim book (unfortunately A4 sized) of 70 pages, which aims to provide practical bedside information for those treating patients with acute pain. It is not intended to be a comprehensive stand-alone book on techniques or a review of the growing literature on Acute Pain Management. The views expressed are those of the members of the Task Force and references are limited.

There are six chapters, covering the mechanisms of acute pain, the pharmacology of opioids, local analgesic drugs and NSAID, adult and paediatric postoperative pain and the management of trauma and burns-related pain. Many readers will consider the book because of their interest in adult postoperative pain—unfortunately there are only 2½ pages on this topic.

The strength of this book, however, lies in the overview of the subject, the coverage of areas such as acutely painful medical conditions and acute cancer pain and the abundance of flow diagrams, tables and lists throughout the book. Errors in dosages have crept in, however; for example, the infusion dose of morphine for neonates is given as 10 *mg* kg^{-1} h^{-1}.

This is a very useful publication designed to be used as a companion to the *U.S. Department of Health Clinical Guidelines on Acute Pain Management*. Between them, they offer a very practical guide to the subject. It is a pity that both are not designed to fit in a white coat pocket.

DOUBLE-LUMEN TUBES

Double-lumen endobronchial tubes (DLT) were introduced originally by Bjork, Carlens and Freiberg [1] for differential bronchospirometry in awake patients. Nowadays, this technique is rarely used and the DLT has become synonomous with anaesthesia for intrathoracic procedures. Its main use is to enable surgeons to perform operations on the so-called quiet or non-dependent, collapsed lung. Naturally, most of these procedures are lung resections but, increasingly, these tubes are also being used during oesophageal, diaphragmatic, skeletal and closed cardiac procedures [2].

The construction and placement of these tubes was governed originally by bronchial anatomy. Indeed, this anatomy has stimulated considerable research into both accurate placement and its confirmation [3]. Over the years, many of these tubes were placed blindly and confirmation based on the old maxim of "looks good, feels good and sounds good". Recent papers, however [4, 5], have questioned if such a maxim is adequate in modern practice.

The major problem has always been the varying origin of the right upper lobe bronchus. Classically, it arises from the lateral wall of the right main bronchus, about 2.5 cm from the carina, and is about 1.5 cm in diameter. However, its origin may vary considerably and it has even been recorded as arising from the trachea [6]. Clearly, the chances of mal-alignment on the right side are much greater than on the left side, where such abnormalities are rarely seen. Consequently, left-sided tubes are more popular than right-sided. Yet, even left-sided tubes may be placed badly and migrate, particularly when the patient is turned from the supine to the lateral position [7].

What steps can be taken to try and reduce the incidence of mal-alignment? There is no doubt that preoperative rigid or fibreoptic bronchoscopy is the first step to enable the anaesthetist to inspect the bronchial tree, particularly the right side, and to note potential difficulties.

The next action, after blind introduction of the DLT, must be to confirm that the tube is in the correct place. Classically, this is performed using cuff inflation, alternate clamping and auscultation. More recently, direct inspection of the bronchial tree with a fibreoptic bronchoscope has been proposed to ensure correct placement [8]. With a left-sided tube in place, it is relatively easy to pass the bronchoscope and visualize the carina between the left upper and lower lobes. With the right-sided tube, the task is more difficult. Not only does the anaesthetist need to define clearly the bronchus intermedius, but he or she must attempt also to manipulate the tip of the bronchoscope into the right upper lobe bronchus. This challenge is another reason why left-sided tubes are preferred for the majority of intrathoracic procedures. Yet, if the left main bronchus is abnormal or a left-sided tube cannot be passed, the right-sided tube should be used. Therefore, it is advisable that anaesthetists with a large thoracic surgical practice should maintain and teach their skills with right-sided tubes.

A second approach, which is novel and published in this edition of the Journal, is to use both pressure and volume loop spirometry [9]. In essence, the patient acts as his/her own control, with subsequent patterns compared against that control. Any alteration between the former and the latter is taken as evidence of mal-alignment. Using this technique, Bardoczky and colleagues have shown that approximately 40 % of all DLT passed in their practice were mal-aligned after fibreoptic bronchoscopy. Further, approximately 66 % of these could be detected using spirometric loops.

What was also of great concern was that, after the turning and positioning of the patient, a further 33 % of tubes migrated from the "initial correct or corrected position". Such a high incidence could certainly account for inadequate ventilation occasionally seen during one-lung anaesthesia. Bardoczky and colleagues adjusted the position of the tubes by using both fibreoptic bronchoscopy and spirometric loops. Thus the modern anaesthetist has additional apparatus to promote increased patient safety.

One of the other complications of the passage of DLT is trauma to the respiratory passages in general, and bronchial rupture in particular [10, 11]. This used to be thought to be caused by faulty technique causing tearing of the bronchial mucosa and splitting of the bronchus. In order to prevent such damage, malleable tubes constructed of p.v.c., with low pressure–high volume cuffs were introduced into clinical practice. In addition, the right-sided tubes had "angled cuffs" to counteract possible mal-alignment with the right upper lobe bronchus [12]. However, investigations have shown that the traditional method of inflating both the tracheal and bronchial cuffs may produce intercuff pressures in excess of 60 cm Hg [13]. This pressure was not only more than twice that required for an efficient seal, but also considerably greater than the capillary arterial pressure. Such large pressures could cause direct ischaemic mucosal damage and possibly lead to bronchial tearing [14]. It may be, therefore, that cuff inflation pressures must be monitored far more carefully in future.

Modern practice using DLT has improved considerably. The onset of breath-to-breath monitoring of end-tidal carbon dioxide, fibreoptic bronchoscopy and spirometry loops have reduced the incidence of complications. In addition, the constant monitoring of oxygen saturation has enabled the safety of patients presenting for thoracic surgical procedures to be improved dramatically over the past decade.

CONTINUOUS SPIROMETRY FOR DETECTION OF DOUBLE-LUMEN ENDOBRONCHIAL TUBE DISPLACEMENT

G. I. BARDOCZKY, M. LEVARLET, E. ENGELMAN AND P. DEFRANCQUEN

SUMMARY

Flow–volume and pressure–volume loops were measured with continuous spirometry in 49 patients in whom the trachea was intubated "blindly" with a double-lumen endobronchial tube for thoracic surgery. Nineteen endobronchial tubes were malpositioned by fibreoptic bronchoscopic criteria; 63% of these were suspected because of the configuration of the spirometric loops. During positioning of the patient and during operation, 34.7% of the endobronchial tubes migrated from the initially correct or corrected position. The secondary displacements were identified by abnormal loop configurations and confirmed with fibreoptic bronchoscopy. Continuous spirometric monitoring is helpful in detecting endobronchial tube displacement during intubation and surgery. (Br. J. Anaesth. 1993; **70**: 499–502)

KEY WORDS

Anaesthetic techniques; fibreoptic bronchoscopy, one-lung ventilation. Intubation: endobronchial. Monitoring: spirometry.

The position of double-lumen endobronchial tubes (DLT) which have been inserted blindly frequently requires correction after fibreoptic bronchoscopic examination [1, 2]. The precisely positioned DLT can be displaced when the patient is moved to the lateral position [3] and may be dislodged during intraoperative manipulation of the pulmonary hilum. Malposition or displacement of the DLT, with subsequent impaired gas exchange, is one of the most difficult situations the anaesthetist may encounter during one-lung ventilation. During operation, the position can be corrected with fibreoptic bronchoscopy or the surgeon can replace the tube manually when the chest is opened. Both procedures are time consuming. Estimation of the dependent lung ventilation is possible [4, 5] by watching mediastinal movements and by monitoring inspiratory airway pressure changes, end-tidal concentration of carbon dioxide and pulse oximetry.

The spirometer of the Ultima SV (Datex Instr. Corp. Helsinki, Finland) provides continuous data on adequacy of ventilation and oxygenation. It incorporates inspiratory airway pressure, volume, flow and end-tidal carbon dioxide measurements at the tracheal tube. The in-line respiratory monitor is supplied with flow–volume and pressure–volume loop displays providing information about the compliance and flow characteristics of the ventilatory system [6, 7]. Changes in compliance and the expiratory flow characteristics are continuously and visually illustrated by the changing form of each loop and can be compared with the baseline curves stored in memory. The visual display of the numeric information may be especially helpful during thoracic surgery. Therefore, the present study was designed to investigate the change in configuration of the displayed loops resulting from malposition or migration of the DLT.

PATIENTS AND METHODS

The study was approved by our hospital's Ethics Committee and informed consent was obtained during a 5-month period from 49 consecutive adult patients undergoing elective right or left thoractomy requiring one-lung ventilation.

Three-lead ECG, invasive radial arterial pressure and arterial oxygen saturation were monitored continuously. The respiratory variables were observed with the flow sensor and gas sampling probe of the Ultima.

Anaesthesia was induced and maintained with a variable rate continuous infusion of propofol; pancuronium was used for neuromuscular block. In all patients, the bronchus of the dependent lung was intubated in a "blind" fashion with a double-lumen endobronchial tube of appropriate size (Broncho-Cath, Mallinckrodt Laboratories, Athlone, Ireland). After intubation, the tracheal and bronchial cuffs were inflated with air and the common connector of the DLT was attached to the flow sensor. Pressure–volume and flow–volume loops were recorded with the two lungs ventilated with 10 ml kg^{-1} tidal volume at a rate of 10–12 b.p.m. To keep the volume constant, the ventilator settings were the same throughout the procedure.

The ability to isolate each lung was assessed by alternately clamping the tracheal and bronchial limbs. The apical, anterior and axillary area of each hemithorax were auscultated, and both limbs were examined for leaks. Pressure–volume and flow–volume loops were recorded again, with the tracheal lumen clamped and judgement was made about the position of the DLT based on the configuration of

GIZELLA I. BARDOCZKY, M.D.; MICHELINE LEVARLET, M.D.; EDGARD ENGELMAN, M.D.; PHILIPPE DEFRANCQUEN, M.D.; Department of Anaesthesiology and Thoracic Surgery, Erasme University Hospital, Free University of Brussels, 808 Route de Lennik, 1070 Brussels, Belgium. FIG. 1. Pressure–volume loops (left panel) and flow–volume loops (right panel) recorded during two-lung ventilation (1) and during one-lung ventilation (2). Upper traces: double-lumen tube placed correctly. Lower traces: double-lumen tube malpositioned.

the loops. Fibreoptic bronchoscopy was then performed to determine if the bronchoscopic findings confirmed the impressions based on the flow– and pressure–volume loops. When the position was not adequate according to the criteria described by Smith, Hirsch and Ehrenwerth [1], it was corrected under direct bronchoscopic examination.

After the patient was placed in the lateral position, the tracheal lumen of the DLT was clamped, flow–volume and pressure–volume loops were recorded and interpreted. Fibreoptic bronchoscopy was repeated and correction of the DLT position was made when required.

During operation and during the period of one-lung ventilation, the flow–volume and pressure–volume loops were monitored continuously. When alteration of the configuration of the curve was noted, recordings were made and fibreoptic bronchoscopy performed. When secondary migration was seen by fibreoptic bronchoscopy, the position of the DLT was corrected.

RESULTS

The mean age of the patients was 57.3 yr (range 14–74 yr), mean height 167 cm (range 151–183 cm) and mean weight was 66.8 kg (range 38–103 kg). In the 49 patients studied; 19 right-sided and 30 left-sided DLT were positioned; 19 (38.7 %) proved to be placed inaccurately during blind intubation (table I). Based on the flow–volume/pressure–volume loop configurations alone, 12 DLT were judged not to be in the satisfactory position after intubation (confirmed by fibreoptic bronchoscopy), and seven other malpositions were recognized by fibreoptic bronchoscopy. From all of the initially correct, or corrected positions, 17 DLT (34.7 %) migrated subsequently: five (10.2 % of all cases) during change to the lateral position and 12 (24.5 %) during surgical manipulation. Sixteen of the 17 secondary displacements were identified by the aberrant pressure–volume and flow–volume curves.

TABLE I. *Position-related problems diagnosed with flow–volume (FV) and pressure–volume (PV) loops and confirmed with fibreoptic bronchoscopy (FOB) in 49 patients in whom the trachea was intubated with a double-lumen endobronchial tube. (Number of right sided double-lumen endobronchial tubes in parentheses)*

Type of malposition	FV/PV loops	FOB
Initial malposition	12 (4)	19 (6)
Postural displacement	5 (2)	5 (2)
Intraoperative migration	11 (3)	12 (4)
Total malpositions	28 (9)	36 (12)

The configuration of the pressure–volume PV loop did not change significantly during one-lung ventilation compared with two-lung ventilation when the DLT was positioned correctly. Only the slope of the curve shifted slightly to the right (fig. 1). When the DLT was placed incorrectly, the form of the pressure–volume curve altered, the inspiratory and expiratory limb becoming distorted and the area of the curve enlarged abnormally (fig. 1).

Of the initially malpositioned DLT, seven were advanced too far, six were not advanced sufficiently and two left-sided tubes were twisted to the right. From the six initially malpositioned right-sided DLT, obstruction of the right upper lobe orifice was noted with fibreoptic bronchoscopy in five instances.

Only one patient exhibited $Sp_{O_2} < 90\,\%$ during one-lung ventilation. Eleven patients had airway pressures > 40 cm H_2O and, on nine occasions,

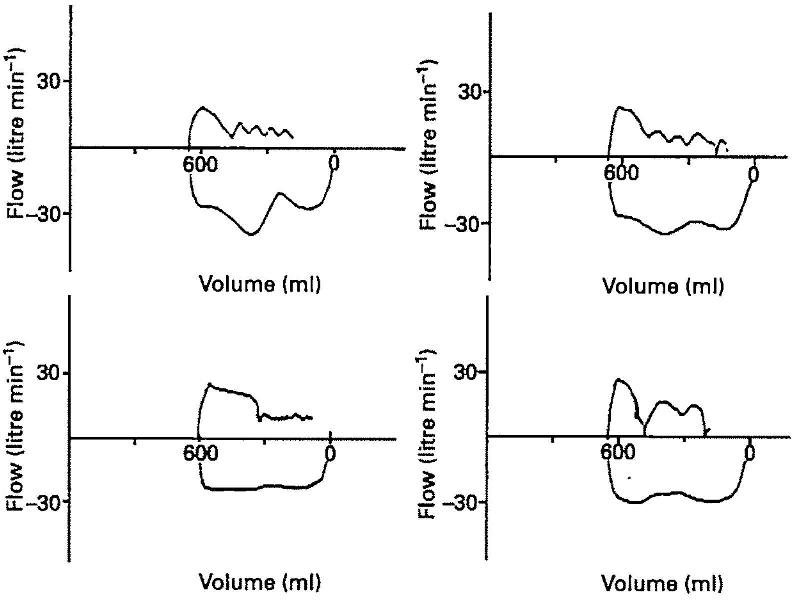

FIG. 2. Flow–volume loops distorted by surgical manipulation.

intrinsic PEEP up to $+9+11$ cm H_2O or persistent expiratory flow was noted on the flow–volume loops during one-lung ventilation.

DISCUSSION

Of the 49 DLT, 19 (38.7 %) were malpositioned and then repositioned with fibreoptic bronchoscopy during initial placement. Of the 19 initial malpositions, 12 (63 %) were suspected because of the configuration of the pressure– and flow–volume loops. The smaller proportion of loop-recognized initial malpositions is likely to be the result of individual variations in the characteristics of the pressure–volume and flow–volume loops in a population with altered lung function. For this reason, a baseline curve has to be established for each patient in the dorsal position during two-lung ventilation. This curve can be stored in the memory of the monitor and compared with those obtained after positioning of the patient and during surgery.

We have not found data in the literature concerning the incidence of secondary displacements. In our study, with continuous spirometric evaluation, 92 % of secondary migrations were identified because of the altered configuration of pressure– and flow–volume curves and confirmed subsequently by fibreoptic bronchoscopy.

The pattern of the flow–volume loop is determined by the mechanical properties of the total respiratory system (the lung and thorax of the patient, the endobronchial tube and the ventilator), but it is reproducible for that given patient. The curve is not very different during two- or one-lung ventilation when the DLT is positioned accurately (fig. 1).

Malposition of a DLT can result in expiratory flow limitation, increased inspiratory or expiratory resistance, or both, because of lumen obstruction and delayed deflation or incomplete emptying of the lung. This results in "cut-off" of the high flow rates and a flat, horizontal expiratory limb (fig. 1). Surgical manipulation around the lung hilum during dissection also changes the pattern of the flow–volume loops, especially the expiratory limb. It becomes ragged or serrated and the expiratory limb may reach the volume axis at a volume greater than zero (fig. 2). Depending on the degree of obstruction caused by the malposition of the endobronchial tube, or by the surgical manipulation of the non-dependent lung, the configuration of the flow–volume loop may be distorted or even grotesque. These loops may illustrate visually the phenomenon of persistent expiratory flow described by Larsson, Malmkvist and Werner [8] (fig. 3). In nine patients, we demonstrated increased end-expiratory pressures during one-lung ventilation, occasionally without increased inspiratory airway pressure. With continuous spirometric monitoring of flow– and pressure–volume loops, large numbers of initial and intraoperative DLT displacements were detected by the altered configuration of either the pressure–volume or the flow–volume loop. As the change of DLT position can be seen immediately from the displayed curves, appropriate action can be initiated, and the harmful effects of increased airway pressure, hyperinflation, hypoventilation and hypoxaemia can be avoided.

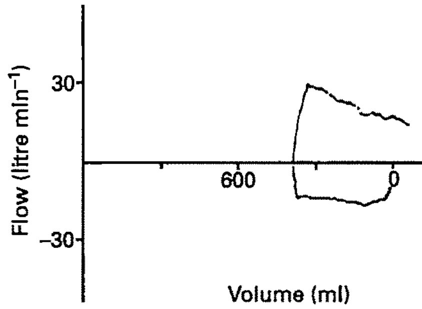

FIG. 3. Flow–volume loop with persistent expiratory flow.

In conclusion, continuous spirometry is a promising method of monitoring ventilation during anaesthesia for lung surgery. The margin of safety of the correct position for the DLT is narrow:

movement of the patient and manipulation can easily displace or dislodge the tube from the correct position. Comparison of the displayed loops with those recorded and considered normal for individual patients is highly desirable, as the curves are slightly different in each patient. Small deviations from baseline can signify a position-related problem, but the exact site and nature of obstruction cannot be diagnosed and corrected based on the altered loop configuration alone. Fibreoptic bronchoscopy is necessary to correct the problem.

PATIENT-CONTROLLED EXTRADURAL ANALGESIA TO COMPARE BUPIVACAINE, FENTANYL AND BUPIVACAINE WITH FENTANYL IN THE TREATMENT OF POSTOPERATIVE PAIN

D. W. COOPER AND G. TURNER

SUMMARY

We have assessed the effect of combining extradural bupivacaine and fentanyl in 60 orthopaedic patients who received 0.125% bupivacaine (bupivacaine group), fentanyl 5 µg ml^{-1} (fentanyl group), or 0.125% bupivacaine combined with fentanyl 5 µg ml^{-1} (combined group), delivered by patient-controlled extradural analgesia for 24 h via a lumbar extradural catheter. Adding bupivacaine to fentanyl reduced mean (SD) fentanyl administration from 117 (46) ml to 89 (42) ml ($P < 0.005$). Adding fentanyl to bupivacaine reduced mean bupivacaine administration from 113 (46) ml to 89 (42) ml ($P < 0.05$). There was no significant difference between the groups in pain, nausea, motor block, pruritus or sedation. No patient had a ventilatory frequency less than 10 b.p.m. Hypotension (systolic AP < 100 mm Hg) occurred in two of 20 patients in the fentanyl group, compared with eight of 19 in the bupivacaine group and 10 of 21 in the combined group. The mean total volume of extradural solution administered was greater after knee replacement (126 (46) ml) than after hip replacement (84 (35) ml) ($P < 0.001$). The mean pain score was greater also for knee replacement (16 (10) mm) than for hip replacement (10 (9) mm) ($P < 0.05$). We conclude that extradural bupivacaine and fentanyl were additive in their analgesic actions, resulting in decreased requirements of each individual agent. Knee replacement was found also to be more painful than hip replacement after operation. (Br. J. Anaesth. 1993; **70**: 503–507)

KEY WORDS

Anaesthetic techniques: extradural. Anaesthetics, local: bupivacaine. Analgesia: patient controlled extradural analgesic. Analgesics: fentanyl. Pain: postoperative.

Extradural analgesia using bupivacaine or opioids, alone or in combination, has become a well established and effective means of controlling postoperative pain. To date, much of the work investigating the combination of bupivacaine and opioids relates to patients in labour. These studies demonstrate that the addition of lipid-soluble opioids to bupivacaine results in improved analgesia [1] and can reduce bupivacaine-related side effects [2]. Whilst the use of the combination of bupivacaine and the lipid-soluble opioid fentanyl is gaining in popularity after surgery, it has been investigated less thoroughly than in obstetric practice. Indeed, recent work has produced conflicting results [3–5].

The aim of this study was to use patient-controlled extradural analgesia (PCEA) to compare extradural bupivacaine, fentanyl and the combination of both, for postoperative pain relief. The concentrations of bupivacaine and fentanyl chosen were those used routinely in combination in our centre for postoperative pain relief by extradural infusion. The use of patient-controlled analgesia (PCA) allows patients to titrate analgesics to their own individual requirements and it has been recommended for use in comparative analgesic studies [6].

PATIENTS AND METHODS

After obtaining Hospital Ethics Committee approval and informed consent, we studied ASA I–III patients undergoing knee or hip replacement surgery, and having an extradural inserted as part of their anaesthetic technique.

Patients were educated in the use of PCEA and the 100-mm visual analogue score before operation. All patients were given a combined extradural and general anaesthetic. Premedication, if required, comprised oral temazepam 1–2 h before operation. A Portex extradural catheter was inserted in a lumbar space before, or shortly after, induction of anaesthesia and an extradural block was established with 0.5% bupivacaine 10–15 ml. The L2–3 or L3–4 space was chosen preferentially, otherwise L1–2 or L4–5 was used according to ease of catheter insertion. After an i.v. induction, anaesthesia was maintained with nitrous oxide and a volatile agent in oxygen. Additional intraoperative analgesia, if required, was provided by fentanyl up to 200 µg i.v.

At the completion of surgery, the extradural catheter was connected to a Graseby PCA machine which was loaded with a preformulated, randomized syringe of extradural trial solution. This contained 0.125% bupivacaine (bupivacaine group), fentanyl 5 $\mu g\ ml^{-1}$ (fentanyl group), or 0.125% bupivacaine combined with fentanyl 5 $\mu g\ ml^{-1}$ (combined group). The PCA settings allowed for a bolus of 4 ml to be given over 5 min with a lock-out time of 10 min. All patients, anaesthetists and nursing staff were blinded to the patient groupings: the syringes were prepared by one of the authors not involved with patient management.

The study lasted for 24 h from the end of the operation, during which time the patients were managed in a High Dependency Unit. Patients were free to use PCEA from the end of the operation. If analgesia was inadequate, as judged by the patient, nursing or medical staff, a maximum of two 10-ml boluses of trial solution, at least 20 min apart, could be given. If analgesia remained inadequate, the study stopped at that point and the correct catheter position was tested with 10 ml of 1% lignocaine. Data were included if motor and sensory block were elicited.

The volume of PCEA solution administered, including bolus doses, was recorded at 4, 8, 12, 16, 20 and 24 h after operation. Visual analogue score (VAS) was recorded on a 100-mm scale (0 mm = no

pain; 100 mm = worst pain imaginable) at 2, 6, 12 and 24 h after operation. Assessments of nausea, motor block, pruritus and sedation were recorded at the same times on 3-, 5-, 4- and 4-point scales, respectively. Arterial pressure and ventilatory frequency were recorded hourly and more frequently if there was hypotension (systolic AP < 100 mm Hg) or respiratory depression (ventilatory frequency < 10 b.p.m.).

Results were compared using Kruskal–Wallis and Mann–Whitney tests with $P < 0.05$ taken as significant.

RESULTS

We studied 60 patients (tables I and II). The three groups were matched evenly in gender, age, weight and type of operation. Relatively more extradurals were sited at L3–4 than L2–3 in the bupivacaine group compared with the fentanyl and combined groups. Patients having knee or hip replacement surgery were matched evenly within age, weight and type of extradural solution. The ratio of females to males was greater and there were relatively more extradurals sited at L3–4 for knee replacement than for hip replacement patients. A tourniquet was used for all knee replacement surgery.

The mean (SD) total volume of extradural solution administered over the 24-h study period was significantly smaller in the combined group (89 (42) ml), compared with the bupivacaine group (113 (46) ml) and the fentanyl group (117 (46) ml) ($P < 0.05$ and $P < 0.01$, respectively) (fig. 1, table III). Supplementary bolus doses were given to four patients in the bupivacaine group (mean volume 14 ml), three in the fentanyl group (mean volume 17 ml) and three in the combined group (mean volume 15 ml). The mean total volume of extradural solution administered was significantly greater for patients having knee replacement (126 (46) ml) than for those having hip replacement (84 (35) ml) ($P < 0.001$). Supplementary bolus doses were given to seven knee replacement patients (mean volume 16 ml) and three hip replacement patients (mean volume 13 ml).

The mean pain scores over the 24-h study period for the fentanyl group (12 (7) mm) and the combined group (11 (10) mm) were smaller than for the bupivacaine group (17 (12) mm), although this was not significant (fig. 2, table III). The mean pain score was significantly greater for knee replacement patients (16 (10 mm) than for those having hip replacement (10 (9) mm) ($P < 0.05$).

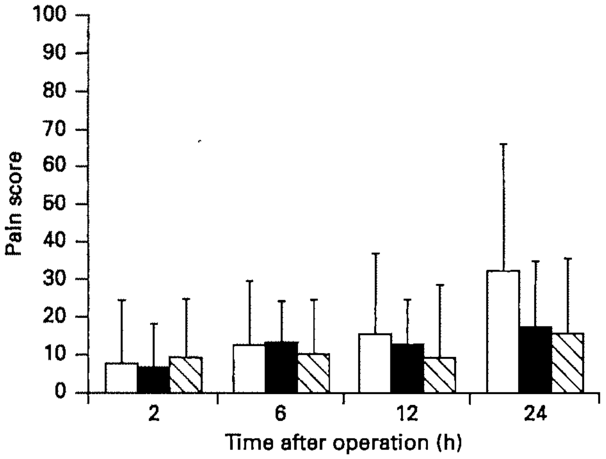

FIG. 2. Mean (SD) pain scores (VAS) for the bupivacaine (□), fentanyl (■) and combined (▨) groups.

TABLE IV. *Percentage of patients in the three groups having nausea, motor block (inability to lift non-operated knee off bed) or pruritus, 2, 6, 12, or 24 h after operation*

	Bupivacaine group	Fentanyl group	Combined group
Nausea (%)	42	40	24
Motor block (%)	53	55	29
Pruritus (%)	16	30	38

Patient gender or positioning of the extradural catheter at L2–3 or L3–4 did not make a significant difference to the volume of solution administered, or pain scores, over the 24-h study period.

Nausea, motor block, pruritus and sedation were not significantly different between the three groups. However, the combined group had less nausea and motor block compared with the two other groups, while the bupivacaine group had less pruritus compared with the fentanyl and combined groups (table IV).

Hypotension (defined as a systolic AP $<$ 100 mm Hg) occurred in four of 19 patients in the bupivacaine group, compared with four of 20 in the fentanyl group and eight of 21 in the combined group after surgery, but before commencement of PCEA. This compared with eight of 19 in the bupivacaine group, two of 20 in the fentanyl group and 10 of 21 in the combined group after commencement of PCEA.

A ventilatory frequency less than 10 b.p.m. was not recorded for any patient after commencement of PCEA. There was no difference in the mean minimum ventilatory frequency between the bupivacaine group (12.8 (1.6) b.p.m.), the fentanyl group (12.5 (2.0) b.p.m.) and the combined group (12.7 (2.1) b.p.m.).

Two patients receiving bupivacaine did not complete the full 24-h study period. One had inadequate analgesia (despite good catheter position) and another found the "numbness" disconcerting and requested withdrawal. A third patient receiving fentanyl requested withdrawal within 2 h because of pruritus. The extradural catheter level was not recorded for this patient.

DISCUSSION

Our results demonstrated that combining extradural bupivacaine and fentanyl decreased requirements of each individual agent. Addition of bupivacaine to fentanyl led to a 24% reduction in fentanyl administration by PCEA, whilst adding fentanyl to bupivacaine led to a 21% reduction in bupivacaine administration by PCEA. This implied that bupivacaine and fentanyl were at least additive in their analgesic actions, and that the contribution of each agent to the combination of both was of a similar magnitude.

These findings differ from those of a similar study [5] using continuous lumbar extradural infusions which found that low-dose bupivacaine did not improve postoperative extradural fentanyl analgesia in orthopaedic patients. That study compared fentanyl 10 $\mu g\ ml^{-1}$ alone and 0.1% bupivacaine combined with fentanyl 10 $\mu g\ ml^{-1}$, given by extradural infusion after knee replacement. The mean doses of bupivacaine and fentanyl administered in the combined group were of the order of 8 $mg\ h^{-1}$ and 80 $\mu g\ h^{-1}$, respectively (ratio of bupivacaine:fentanyl = 1 mg:10 μg). This compared with mean doses of bupivacaine 5.8 $mg\ h^{-1}$ and fentanyl 23 $\mu g\ h^{-1}$ for the knee replacement patients in our combined group (ratio of bupivacaine:fentanyl = 1 mg:4 μg). We suggest that the relatively large dose of fentanyl used in that study may have masked any beneficial effect of the addition of bupivacaine to fentanyl.

More recent work [3], comparing continuous thoracic extradural infusions of 0.2% bupivacaine, fentanyl 10 $\mu g\ ml^{-1}$ and a combination of both, after abdominal aortic surgery, is in greater concordance with our results. In that study, the combined group had superior analgesia compared with each agent used alone. A mean dose of bupivacaine 9.3 $mg\ h^{-1}$ and fentanyl 46 $\mu g\ h^{-1}$ was administered. Whilst the concentrations and doses of bupivacaine and fentanyl used were greater, the dose ratio of the two (1 mg:5 μg) was similar to that used in our study (1 mg:4 μg). The optimum dose ratio for extradural bupivacaine and fentanyl is likely to be closer to these values than that used in the orthopaedic study of Badner and colleagues [5].

The side effects encountered in our study were of a minor nature. There was no significant difference between the groups for nausea, motor block, pruritus or sedation. Respiratory depression (ventilatory frequency < 10 b.p.m.) was not encountered in any group. A systolic AP of < 100 mm Hg was recorded in 20 of 60 patients after commencement of PCEA. In the study comparing similar groups after aortic surgery [3], no patient had a systolic AP of less than 100 mm Hg. It is possible that the administration of small boluses of bupivacaine (5 mg) by PCEA in our study, as opposed to a continuous infusion, contributed to this difference. A more likely explanation is that the invasive monitoring used in the aortic patients enabled more rapid detection and treatment of hypovolaemia, thus preventing hypotension. The problem of postoperative hypotension should be balanced against the reduction in extradural fentanyl requirements and possible reduction in deep vein thrombosis [7] produced by extradural bupivacaine.

A coincidental finding in our study was that, after knee replacement, 50% more extradural solution was used than after hip replacement. Despite this, the average pain score was significantly greater than after hip replacement. We conclude that knee replacement was more painful than hip replacement.

The technique of PCEA was accepted well by this rather elderly group of patients. It allowed patients to administer analgesia more closely to their widely varying individual needs. However, all groups did not quite achieve uniformly low pain scores, in particular the bupivacaine group at 24 h after operation had a greater mean pain score than the two other groups (fig. 2). This may have resulted from regression and tachyphylaxis [8, 9] but, if so, we cannot explain why the patients did not increase the bupivacaine administration to counter this.

There may be advantages in using PCEA routinely. The average hourly amount of bupivacaine or fentanyl used after knee replacement by patients with PCEA in our study was of the order of 33% of that reported for patients with continuous extradural infusions after knee replacement [5, 10]. This is in agreement with a study comparing administration of fentanyl by either PCEA or continuous extradural infusion following abdominal surgery [11]. It was suggested that psychological or pharmacological mechanisms may be responsible for this difference. Reduction in anxiety may have increased the placebo effect of PCEA. Intermittent bolus administration of drugs may have allowed greater CSF penetration of fentanyl than a continuous infusion. In addition, spread of extradural solution after bolus administration may be greater than with infusion. This is more likely to be a factor for fentanyl than for bupivacaine. In order to block knee or hip pain, the spinal analgesic action of fentanyl would occur in the lower thoracic region, as opposed to the lumbar region for bupivacaine. Whatever the mechanism, the potential for PCEA to reduce analgesic dosage, whilst at the same time maintaining analgesic efficacy, warrants further investigation.

ACKNOWLEDGEMENTS

We thank Astra Pharmaceutical for supplying all the extradural solutions and Graseby for loaning us the PCEA pumps.

EFFICACY OF CONTINUOUS INTERCOSTAL BUPIVACAINE FOR PAIN RELIEF AFTER THORACOTOMY

C. M. DRYDEN, I. McMENEMIN AND D. J. R. DUTHIE

SUMMARY

*We studied 20 patients undergoing thoracotomy, in a double-blind, placebo-controlled crossover trial of intercostal bupivacaine. Bupivacaine 0.25% was infused at 5 ml h^{-1} through each of two catheters placed in the intercostal space at operation. Mean (95% confidence limits) 24-h requirements for morphine from a patient-controlled analgesia device were 29 (22–37) mg during bupivacaine infusion and 44 (32–57) mg during saline infusion (*P = *0.04). Patients also recorded significantly smaller visual analogue scores for pain during bupivacaine infusion. There were no adverse effects related to the intercostal infusion of bupivacaine. We conclude that bupivacaine, infused through catheters placed during thoracotomy in the adjacent intercostal spaces, is a useful adjunct to systemic opioid analgesia* (Br. J. Anaesth. 1993; **70**: 508–510)

KEY WORDS

Anaesthetic techniques, regional: intercostal block. Pain: postoperative.

Lateral thoracotomy wounds are amongst the most painful [1], but local anaesthetic in the intercostal space has been shown to relieve pain after thoracotomy effectively [2]. Problems associated with percutaneous intercostal nerve block include intravascular injection, puncture of the parietal pleura and a significant failure rate [3, 4]. The risks are increased if repeated injections are used, rather than a catheter technique. Bupivacaine delivered via catheters placed in the intercostal space during surgery has been described recently as a means of providing analgesia after thoracotomy [5]. Our study was designed to assess the analgesic efficacy after thoracotomy of continuous intercostal nerve block compared with placebo.

PATIENTS AND METHODS

After obtaining local Ethics Committee approval and informed written consent, we studied patients admitted for elective surgery through a single lateral thoracotomy incision. Patients were instructed how to use a patient-controlled analgesia device (Graseby 2000, Graseby Medical Ltd, Watford, U.K.). Anaesthetic technique was standardized. Benzodiazepine premedication was provided and anaesthesia was induced with etomidate 0.3 mg kg^{-1}. Anaesthesia was maintained with 0.5–1.5% enflurane and 50% nitrous oxide in oxygen, supplemented with morphine 10 mg i.v. Vecuronium 0.1 mg kg^{-1} i.v. with further increments of 0.03 mg kg^{-1} as required was used to facilitate mechanical ventilation of the lungs. Neuromuscular block was antagonized subsequently with neostigmine 2.5 mg and glycopyrronium 0.5 mg i.v. Immediately before closure of the chest, two 16-gauge extradural catheters (Portex Ltd, Hythe, U.K.) were placed under direct vision, in the intercostal spaces immediately above and below the wound, by feeding the catheters posteriorly from the wound edges, superficial to the parietal pleura, and bringing the catheters out through the chest wall using the Tuohy needles.

Patients were allocated randomly to group A or group B using sealed envelopes. The trial was designed as a crossover study with patients receiving either 0.25% bupivacaine for the first 24 h and saline for the second (group A), or saline for the first 24 h, followed by bupivacaine (group B). The solutions were infused continuously at a rate of 5 ml h^{-1} through each of the two intercostal catheters. Each catheter was primed with 10 ml of the appropriate solution. Both patient and investigator were blind to the nature of the solution.

On regaining consciousness, patients were given further increments of morphine 1–2 mg i.v. until they were comfortable and able to operate the patient controlled analgesia device (PCA). The PCA device was programmed to deliver morphine 1 mg i.v., with a lock-out duration of 3 min.

Morphine consumption from the PCA was recorded hourly throughout the 48 h of the study period. The patients performed visual analogue scores (VAS) of pain on a 100-mm horizontal line at 1, 3, 6, 24 and 48 h after operation. At 4-h intervals, nursing staff graded and recorded the level of pain, sedation and nausea using the scoring systems detailed in table I.

Lopamidol 10 ml (Niopam 300) was injected through the intercostal catheters, before routine

TABLE I. *Scoring systems used by nursing staff to assess pain, sedation and nausea*

Pain	Sedation	Nausea
0 Asleep	1 Fully awake	0 Nil
1 Awake+no pain	2 Slightly drowsy	1 Nausea
2 Mild pain	3 Very drowsy	2 Vomiting in last 1 h
3 Moderate pain	4 Asleep	
4 Severe pain		

postoperative radiography in the recovery room, to confirm correct placement of the catheters and to outline the likely route of spread of local anaesthetic solution.

Statistical significance was tested using one-way analysis of variance for morphine consumption data. The Kruskal–Wallis test was used for VAS data and chi-square test for scores assessed by nursing staff. Statistical significance was accepted when $P < 0.05$.

RESULTS

Twenty-two patients entered the study. One patient required mechanical ventilation after operation and the PCA device suffered malfunction during another case. Complete data were available therefore for 20 patients. Details of the patients' characteristics and of surgical procedure are given in table II.

Patients consumed less morphine while receiving intercostal bupivacaine than while receiving intercostal saline (table III). The 24-h morphine requirements of group A patients decreased by a mean (95% confidence limits) of 3.90 (−8.4, 16.2) mg for day 2 (saline) compared with day 1 (bupivacaine). The 24-h morphine requirements of group B patients decreased by a mean of 34.10 (13.0, 55.2) mg for day 2 (bupivacaine) compared with day 1 (saline) ($P = 0.01$).

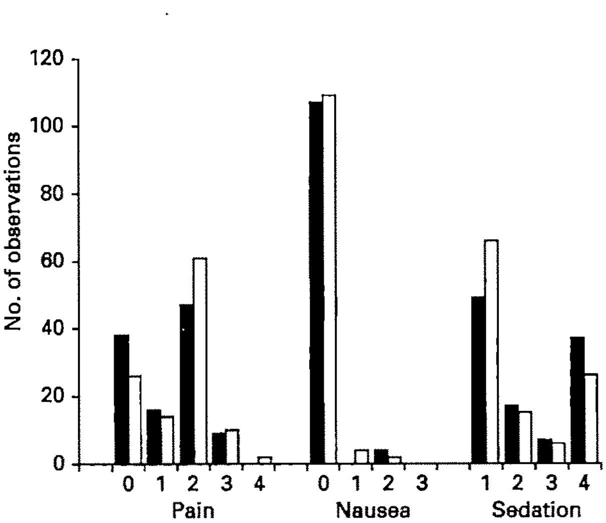

FIG. 1. Distribution of observations recorded by nursing staff for pain, nausea and sedation, after bupivacaine (■) or saline (□), using the system described in table I.

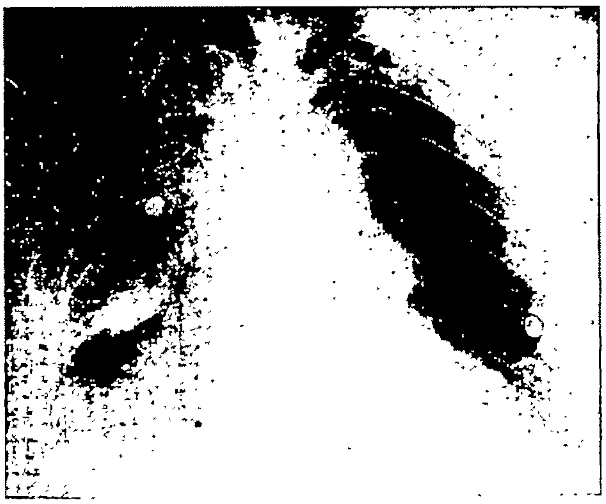

FIG. 2. Representative portable AP chest radiograph taken immediately after surgery, showing spread of contrast medium injected through intercostal catheters.

Patients recorded smaller visual analogue scores of pain while receiving bupivacaine (table IV).

Scores assessed by nursing staff for pain, sedation and nausea did not differ in patients receiving either bupivacaine or saline (fig. 1).

Radiography demonstrated spread of contrast medium along the intercostal space and the ipsilateral paravertebral space (fig. 2).

DISCUSSION

Administration of bupivacaine by the intercostal route reduced the requirement for morphine after thoracotomy. Individual requirements for postoperative analgesia vary greatly, but the crossover design of this study allowed each patient to act as his or her own control. Analgesic requirements would be expected to decrease over the 48-h period of the study, but this should affect both groups A and B similarly.

Patients recorded smaller visual analogue scores of pain while receiving bupivacaine. This suggests that patients were more comfortable with intercostal bupivacaine and self-administered morphine than with self-administered morphine alone.

There were no differences in the nursing assessment of degree of pain, sedation and nausea between patients when receiving bupivacaine or placebo. This may reflect the insensitive nature of the scoring systems used.

The radiographic demonstration of contrast medium in the paravertebral space suggests that paravertebral block contributed to the efficacy of this technique. It has been demonstrated previously that intercostal injections spread via the paravertebral space [3, 4, 6]. However, it should not be assumed that an intercostal injection of contrast medium and an intercostal infusion of bupivacaine behave similarly. Morphine consumption by patients during bupivacaine infusion was greater than would be expected (mean 29 mg, 95 % CL 22, 37 mg) if paravertebral block was significant. In a study of bupivacaine infused into the paravertebral space after thoracotomy, the mean requirement for papaveretum was 14 mg in the first 48 h [7]. Sources of pain after thoracotomy potentially covered by paravertebral but not by intercostal block include the ribs and costochondral joints, viscera and the chest drain site [8].

No patient in this study required treatment for hypotension or catheterization for urinary retention, which compares favourably with extradural analgesia [9]. The technique described here had the further attraction that placement of the catheters was performed under direct vision, increasing the incidence of correct positioning whilst also reducing the risks of injury to the lung and of intravascular placement.

Although the intercostal space is highly vascular, with rapid absorption of local anaesthetics [10], the dose of bupivacaine required for this technique ($25\ \mathrm{mg\ h^{-1}}$) is well below the recommended safety limit of $2\ \mathrm{mg\ kg^{-1}}$ in any 4-h period. Chan and colleagues [5] injected 0.5 % bupivacaine 10 ml with adrenaline 6-hourly through intercostal catheters. They studied six patients for 48 h after thoracotomy and found plasma concentrations of bupivacaine to be less than $4\ \mu\mathrm{g\ ml^{-1}}$.

We conclude that a continuous intercostal infusion of bupivacaine is associated with a low incidence of complications, and provides an effective adjunct to systemic opioids in the relief of pain after thoracotomy.

MORPHINE-6-GLUCURONIDE DISPOSITION IN RENAL IMPAIRMENT

M. H. HANNA, F. D'COSTA, S. J. PEAT, C. FUNG, N. VENKAT, T. R. ZILKHA AND S. DAVIES

SUMMARY

Twelve patients with chronic renal failure (dialysis-dependent) and six with good renal function after renal transplantation received i.v. morphine-6-glucuronide (M6G) 30 $\mu g\ kg^{-1}$ as part of a standardized anaesthetic technique for minor surgery. Continuous peritoneal dialysis was commenced 6 h after M6G administration in six of the dialysis-dependent patients. Serum was sampled for up to 12 h and analysed for morphine and M6G by high pressure liquid chromatography. Morphine was not detected. Mean (SD) derived pharmacokinetic variables for the three groups (transplant, renally impaired non-dialysed and renally impaired dialysed, respectively) were: elimination half-life 2.14 (0.69) h, 27.10 (15.8) h, 17.33 (4.6) h; clearance 96.0 (34.9) ml min^{-1}, 10.57 (5.57) ml min^{-1}, 14.3 (6.2) ml min^{-1}; volume of distribution 0.19 (0.03) litre kg^{-1}, 0.25 (0.06) litre kg^{-1}, 0.27 (0.06) litre kg^{-1}. The elimination half-life was shorter ($P < 0.01$) and the clearance greater ($P < 0.01$) for the transplanted group compared with the dialysed and non-dialysed groups. Peritoneal dialysis for the second 6 h after drug administration had little effect on M6G disposition as assessed by comparison with data obtained from the non-dialysed group. (Br. J. Anaesth. 1993; **70**: 511–514)

KEY WORDS

Analgesics: morphine-6-glucuronide. Kidney: peritoneal dialysis, renal failure. Pharmacokinetics.

The morphine metabolite morphine-6-glucuronide (M6G) is a potent analgesic in animals [1–4] and man [5, 6]. Its analgesic action appears to be mediated via a mechanism similar to that proposed for morphine [2], but it has a greater potency, a longer duration of action and a smaller ED_{50}: LD_{50} ratio [1–4, 6].

There are large unexplained variations in clinical dose requirements and dynamic responses to morphine. This could be accounted for partly by factors such as age, disease, nature and severity of pain, and the use of concomitant medication [7]. Variations in response may also be secondary to interindividual variability in the pharmacokinetic properties of morphine and its 3- and 6-glucuronide metabolites [8]. Morphine-3-glucuronide (M3G) and M6G quickly attain plasma concentrations exceeding those of the parent drug after both single and multiple dosing with morphine, irrespective of the route of administration [9, 10]. The presence of active metabolites in such large quantities may further complicate the unpredictable pharmacodynamic response to administration of the parent drug.

Renal impairment does not significantly change morphine disposition when assessed by specific assays not subject to interference by the presence of metabolites [8, 11–15]. Increased concentrations of M6G and M3G after administration of morphine to these patients has been well documented [11, 13–15]. The nature of morphine glucuronide disposition in patients with renal impairment has considerable clinical implications and necessitates careful assessment.

Definition of the contribution of active metabolites to the therapeutic or toxic effects that occur after administration of the parent compound is difficult [16, 17]. In order to gain a clear understanding of this contribution, kinetic and dynamic investigations of the metabolite in the absence of the parent drug and in a clinically relevant setting are necessary. The present study is the first to investigate the pharmacokinetics of i.v. M6G in patients with functioning renal transplants and chronic renal impairment, and to examine the effect of peritoneal dialysis on its kinetic profile.

PATIENTS AND METHODS

After obtaining Ethics Committee approval and written informed consent, we studied 18 patients with chronic renal impairment presenting for minor surgery under general anaesthesia. Six had good renal function after renal transplantation and 12 were dependent on peritoneal dialysis. Dialysis-dependent patients were allocated randomly to two groups: those in group 1 were not dialysed during the study; those allocated to group 2 underwent continuous peritoneal dialysis (hourly 1-litre cycles) commencing at 6 h after administration of M6G and continuing for the remainder of the study. All patients were fasted for 6 h before operation and i.v.

fluids were not administered. Non-invasive cardiorespiratory monitoring (automated oscillometer and pulse oximeter) and venous cannulation were performed before induction of anaesthesia and maintained throughout the study. All patients received i.v. M6G 30 $\mu g\ kg^{-1}$ over 4 min at induction of anaesthesia as part of a standardized anaesthetic technique. Anaesthesia was induced using propofol 2.5 $mg\ kg^{-1}$ and patients were subsequently allowed to breathe spontaneously a mixture of 50 % nitrous oxide and 1–2 % isoflurane in oxygen. Venous blood samples were taken from a cannula in the opposite limb before, and at 5, 10, 15, 20, 40, 60, 80, 120, 160, 200, 240, 280, 320 and 360 min after administration of M6G, then hourly for another 6 h.

The samples were separated by centrifugation and the supernatant stored at −20 °C until analysis for morphine and M6G by high pressure liquid chromatography with electrochemical detection in accordance with an assay technique described previously [18, 19]. Calibration curves were constructed daily for morphine and M6G using standards obtained from Evans Medical (morphine) and Ultrafine Chemicals (M6G). These were linear with coefficients greater than 0.997. Each sample was analysed once. The lower limit of detection was 1 $ng\ ml^{-1}$ for both morphine and M6G.

Derived pharmacokinetic parameters were calculated by weighted, interactive, computer-assisted non-linear regression analysis [20, 21] using a two-compartment model for all patients. Pharmacokinetic and biochemical data obtained for the three groups (transplanted, renally impaired and renally impaired dialysed) were compared using the Mann–Whitney U test.

TABLE I. *Pre-trial data for patients entered into the study. Patients with renal transplants had significantly smaller pre-trial creatinine concentrations than those who were dialysis-dependent* ($P < 0.01$ *for patients allocated to the dialysis group and non-dialysis groups*) (*mean* (SD) [*range*])

	Age (yr)	Weight (kg)	Creatinine (mmol $litre^{-1}$)
Transplant	45.90	86.67 (20.83)	130.5 (26.0)
($n = 6$)	[33.0–56.25]	[63.5–113.2]	[103–176]
Non-dialysed	48.68	73.57 (12.28)	696.7 (296.4)
($n = 6$)	[18.5–66.83]	[53.0–86.0]	[206–983]
Dialysed	58.87	73.75 (15.24)	660.7 (361.1)
($n = 6$)	[34.17–69.67]	[57.0–101]	[325–1103]

RESULTS

Of the 12 patients with dialysis-dependent renal impairment, six were allocated to group 1 (non-dialysed) and six to group 2 (dialysed). The three groups were similar in age, weight and serum albumin concentrations (table I). The serum creatinine concentrations for both group 1 and group 2 were significantly greater than those for the transplanted group ($P < 0.01$ in each case) (table I). The patients were receiving a wide variety of medication including vitamins, antibiotics, alfacalciferol, insulin, vasodilators, H_2 antagonists, phosphate binding agents, antibiotics, antihypertensives, antidepressants and calcium carbonate. Those with functioning transplants were receiving immunosuppressive therapy (azathioprine and prednisolone with or without cyclosporin). The nature and duration of surgery was similar in all three groups, consisting of vascular access surgery and insertion and removal of peritoneal dialysis catheters. One patient (in the transplant group) underwent repair of a small incisional hernia. The maximum duration of surgery was 20 min. Oxygen saturation remained greater than 95 % in all patients throughout the study. Arterial pressure, heart rate and ventilatory frequency recorded for patients in the three groups were similar and remained within a clinically acceptable range of values. There were no adverse reactions in any patient.

Morphine was not detected in any samples. The elimination half-lives obtained in both the non-dialysed and dialysed groups were significantly longer than those obtained for the transplant group ($P < 0.01$ in each case) and the values obtained for clearance were significantly smaller ($P < 0.01$ in each case) (table II). The volumes of distribution were similar in all three groups (table II).

Peritoneal dialysis (started 6 h after administration of M6G) had little effect on pharmacokinetic parameters obtained for M6G as assessed by comparison with data obtained from the non-dialysed group.

DISCUSSION

There has been increasing debate on the disposition and metabolism of morphine in patients with renal insufficiency and its association with adverse reactions [22]. Morphine disposition is not usually

altered in uraemic patients [8, 12, 13], but clinical data indicate that patients with renal failure are particularly susceptible to the toxic effects of morphine, and may have small dose requirements for analgesia [2, 8, 15, 23–25]. Hypotheses advanced to explain this include systemic metabolite deconjugation, biliary excretion of glucuronides and deconjugation by gut flora, increased enterohepatic circulation of morphine and accumulation of large quantities of active metabolites [2, 8, 15, 24, 26]. The pharmacokinetic profile of M6G as a morphine metabolite (M6Gi) has been investigated in patients with renal impairment, and a prolonged half-life demonstrated [11, 15, 25].

The absence of morphine in serum after the administration of M6G presented here excludes systemic deconjugation (or enteral deconjugation and reabsorption) sufficient to generate detectable quantities of the parent drug. The pharmacokinetic data presented here, relating to direct administration of M6G, have demonstrated that renal impairment was associated with a considerable delay in removal of M6G from the plasma compartments (fig. 1). Further analysis of the data demonstrates that renal impairment was associated with prolongation of the M6G terminal elimination half-life ($T_{\frac{1}{2}}^{\beta}$) and a reduction in M6G clearance (Cl) with no change in volume of distribution (Vd). Although Vd and Cl are independent terms, they are determinants of $T_{\frac{1}{2}}^{\beta}$ as follows:

$$T_{\frac{1}{2}}^{\beta} = \frac{0.69\ V\mathrm{d}}{Cl}$$

Thus the prolongation of M6G $T_{\frac{1}{2}}^{\beta}$ for patients with renal impairment is a direct reflection of reduced clearance, indicating that clearance is highly dependent on a functioning kidney. It may be concluded that accumulation of M6Gi in patients with renal impairment given morphine is secondary to the pharmacokinetic characteristics of the metabolite rather than to those of the parent drug. This confirms a previous case report [5].

Morphine and M6G bind to mu receptors stereospecifically with high affinity, although they have different affinities for the mu subtypes [2–4, 26]. Receptor binding in the biophase, and the consequent clinical effects, are subject to a complex array of competing influences ranging from the physicochemical characteristics of the drug to physiological changes in the patient. It is, nonetheless, curious that we did not observe prolonged respiratory depression, in view of the relatively large concentrations attained. In patients with renal impairment, persistently increased concentrations of systemic M6Gi after multiple dosing with morphine may be expected to facilitate entry of M6Gi to the CSF and biophase, and M6G elimination from the CSF compartment appears to occur more slowly than that of the parent drug [6]. Central accumulation of M6Gi could therefore explain toxicity occurring at relatively small systemic concentrations. Alterations in the response of patients secondary to uraemia, drug interactions, increased blood–brain permeability, changes in protein binding and receptor affinity, or the presence of other opioids must also be considered.

The pharmacokinetic parameters obtained in the transplant group of this study were similar to those reported for normal (awake) volunteers [27, 28], demonstrating that patients with good renal function after transplantation are able to clear M6G effectively. Comparison of the data obtained in these two studies suggests that the effect of general anaesthesia on M6G disposition in patients with functioning renal transplants is minimal. The findings of an investigation into the effect of general anaesthesia on the elimination of morphine and its glucuronides in healthy patients implied that anaesthesia delayed M6Gi excretion, possibly secondary to a reduction in renal blood flow [29]. The apparent discrepancy between these results and the findings of the present study may reflect the differing responses of the normal and transplanted kidney to the stress of anaesthesia and surgery, possibly secondary to the lack of graft innervation and failure to modulate renal blood flow.

Six hours continuous peritoneal dialysis had little effect on M6G disposition. M6G has a low Vd ($<$ 0.5 litre kg^{-1}) and, in patients with renal impairment, a prolonged $T_{\frac{1}{2}}^{\beta}$, suggesting that, providing it crosses the peritoneal membrane easily, it is removed efficiently by dialysis. Our results, and data from a previous case report [2] suggest that this is not so. Drug elimination by peritoneal dialysis is inefficient if the dialysate flow rate is low, if its volume of distribution in the dialysate is small compared with its total volume of distribution, or if the contribution of peritoneal dialysis to total body clearance is insignificant because of the simultaneous presence of other routes of removal [30]. Investigation of the physicochemical characteristics of M6G, particularly its degree of protein binding and ionization, may help to explain its pharmacokinetic profile in dialysis-dependent patients.

PARTIAL REVERSAL OF THE EFFECTS OF EXTRADURAL CLONIDINE BY ORAL YOHIMBINE IN POSTOPERATIVE PATIENTS

N. LIU, F. BONNET, L. DELAUNAY, N. KERMAREC AND G. D'HONNEUR

SUMMARY

Extradural clonidine produces analgesia, with sedation, hypotension and bradycardia, in postoperative patients. This study assessed if oral yohimbine would reverse these side effects. We studied 30 ASA I–II patients undergoing orthopaedic surgery. After operation they were allocated randomly to three groups to receive placebo, extradural clonidine 450 μg or extradural clonidine 450 μg plus oral yohimbine 16 mg. Pain score was measured on a visual analogue scale (VAS); sedation was assessed on a simple scale graded from 0 (awake and alert) to 3 (deeply sedated, awakening after tactile stimulations) and heart rate and arterial pressure were monitored for 5 h. Yohimbine reversed the sedation induced by extradural clonidine, but also shortened the duration of analgesia (31 (SD 15) min, 186 (72) min and 126 (52) min in the placebo, extradural clonidine and extradural clonidine+yohimbine groups, respectively) ($P < 0.05$), and did not reduce the hypotension and bradycardia related to clonidine administration. These results suggest that alpha$_2$ adrenoceptors are mediators of the sedation induced by clonidine and that the haemodynamic effects are not related to stimulation of supraspinal alpha$_2$ receptors. (Br. J. Anaesth. 1993; **70**: 515–518)

KEY WORDS

Anaesthetic techniques: extradural. Pain: postoperative. Sympathetic nervous system, alpha$_2$ adrenergic agonists: clonidine; alpha$_2$ adrenergic antagonists: yohimbine.

Clonidine produces analgesia in laboratory animals and in postoperative patients via alpha$_2$ adrenoceptors located in the dorsal horn of the spinal cord [1–4]. Systemic absorption of clonidine occurs after extradural administration and is considered responsible for the side effects of hypotension, bradycardia and sedation which may limit its use for postoperative analgesia [1, 2, 5–7]. Yohimbine is an alpha$_2$ adrenoceptor antagonist which reverses both analgesia and side effects induced by alpha$_2$ agonists in animals [3, 4, 8, 9]. Naloxone has been reported to reverse side effects induced by extradural morphine while analgesia was unchanged, because of a favourable balance between agonist and antagonist at the level of the spinal cord while antagonist effectively competes with agonist at the other sites of action responsible for side effects [10]. It may be postulated that the oral administration of yohimbine might reverse the side effects of extradural clonidine while analgesia would be maintained. This study, performed in postoperative patients, was designed to evaluate this hypothesis.

PATIENTS AND METHODS

After obtaining institutional Ethics Committee approval and informed consent, we studied 30 ASA I patients undergoing orthopaedic surgery. Patients who were receiving alpha$_2$ adrenoceptor agonists, neuroleptics, tricyclic antidepressants or beta blocking agents were excluded from the study.

Surgery of the lower limbs was performed under extradural anaesthesia using 0.5% bupivacaine. After operation, in the recovery room, patients were allocated randomly to three groups when they had recovered from local anaesthetic block and complained of pain. In the first group, patients received an oral placebo and 10 ml of an extradural isotonic saline solution, the second group received an oral placebo and extradural clonidine 450 μg diluted in 10 ml of an isotonic solution and the third group received the same dose of extradural clonidine and yohimbine 16 mg orally. The dose of oral yohimbine was determined from a previous open study, as the minimal dose necessary to reverse sedation induced by extradural clonidine 450 μg.

Patients rated their pain using a visual analogue scale (VAS) graded from 0 (no pain) to 10 (maximum pain) [11] before administration of the test drugs, then every 15 min for the first 1 h and then every 1 h for 6 h. At the first complaint of pain after extradural administration of clonidine or placebo, patients were given paracetamol 500 mg i.v. VAS scores after paracetamol were excluded from analysis and comparisons between groups. We determined the duration of action of extradural clonidine or placebo by the time elapsed between clonidine or placebo administration and the first paracetamol injection.

Sedation was measured by a blinded observer on a scale graded as follows: 0 = fully conscious; 1 = sleepy awakening spontaneously; 2 = sleepy awak-

TABLE I. *Patient data (mean (range or* SD*))*

	Sex (M/F)	Age (yr)	Weight (kg)	Height (cm)
Placebo	5/5	49 (18–78)	70 (13)	169 (10)
Clonidine	5/5	43 (18–56)	72 (15)	169 (9)
Clonidine + yohimbine	4/6	42 (21–71)	67 (12)	168 (10)

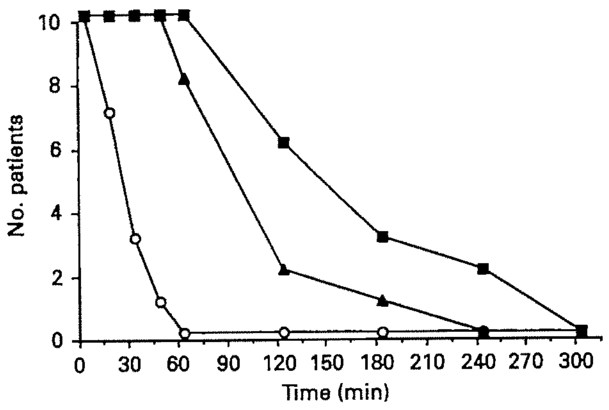

FIG. 1. Number of patients who did not require further analgesia after extradural injection ($n = 10$ in each group). $P < 0.05$ for clonidine (■) and clonidine + yohimbine (▲) groups compared with placebo group (○).

ening after verbal stimulations; 3 = drowsy awakening after tactile stimulations; 4 = comatose. Patients were evaluated for sedation simultaneously with VAS measurements. Arterial pressure and heart rate were measured before and every 5 min throughout the study using an automatic oscillotonometer (Dinamap, Critikon).

Values are expressed as mean (SD). Statistical analysis used a two-way ANOVA for repeated measures and Student's *t* test. Duration of analgesia were compared using the Kaplan Meier method and a log-rank test. Differences were considered significant when $P < 0.05$.

RESULTS

Patient data were comparable in the three groups (table I). Duration of analgesia was prolonged significantly in patients receiving clonidine or clonidine + yohimbine compared with placebo (31 (SD 15) min in the placebo group, 186 (72) min in the clonidine group and 126 (52) min in the clonidine + yohimbine group) ($P < 0.05$). The difference was also statistically significant between patients receiving extradural clonidine and extradural clonidine with oral yohimbine. After extradural administration, patients in the placebo group required i.v. paracetamol more rapidly than in the clonidine or clonidine + yohimbine groups (fig. 1). VAS values were also significantly smaller in patients receiving clonidine with or without yohimbine over the first 2 h (fig. 2). Two hours after the extradural injection, all the patients in the placebo group and eight of 10 patients in the clonidine + yohimbine group had been given i.v. paracetamol and were excluded from comparative analysis of the VAS scores.

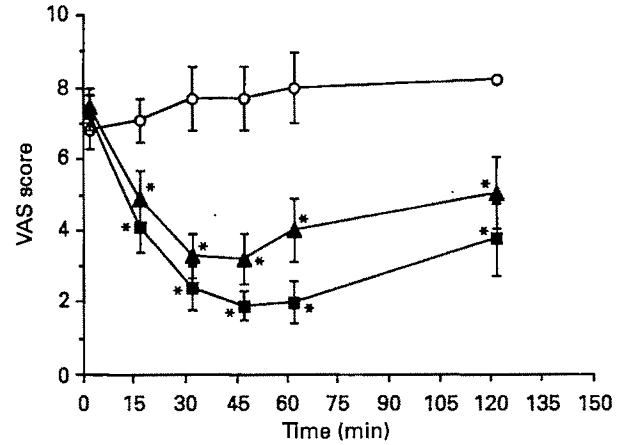

FIG. 2. Changes in VAS scores in the three groups of patients over the first 120 min. ■ = Clonidine; ▲ = clonidine + yohimbine; ○ = placebo. *$P < 0.05$ compared with placebo.

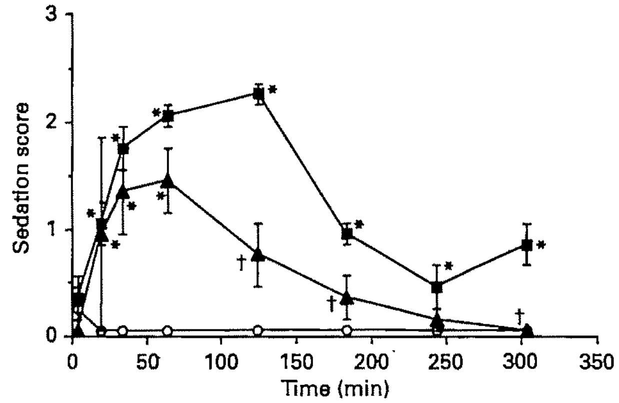

FIG. 3. Sedation scores in the three groups of patients. $P < 0.05$: * compared with placebo (○); † compared with clonidine (■). ▲ = Clonidine + yohimbine.

Significantly greater sedation scores were noticed in the clonidine group compared with placebo (fig. 3). The addition of oral yohimbine partly reversed ($P < 0.05$) sedation induced by clonidine (fig. 3). Significant decreases in arterial pressure and heart rate were noticed in patients who received extradural clonidine (figs 4, 5). Oral yohimbine had no significant effect on hypotension or bradycardia induced by extradural clonidine. Nevertheless, none of the patients in this study required treatment for hypotension or bradycardia.

DISCUSSION

We have shown that the oral administration of yohimbine partly reversed not only sedation induced by extradural clonidine, but also analgesia; however, it failed to alter significantly the changes in arterial pressure and heart rate at the doses of clonidine used. Clonidine-induced sedation is thought to be mediated by stimulation of alpha$_2$ adrenoceptors in the locus coeruleus and is reversed by yohimbine in animals [12]. In veterinary practice, yohimbine is commonly used to reverse sedation induced by the related compound, xylazine [9, 13–15].

After extradural administration, clonidine may reach supraspinal sites responsible for sedation, by

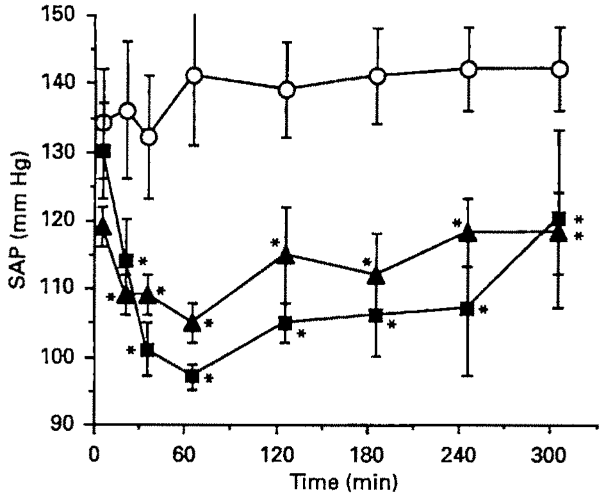

FIG. 4. Changes in systolic arterial pressure in the three groups. ■ = Clonidine; ▲ = clonidine+yohimbine; ○ = placebo. $*P < 0.05$ compared with placebo.

systemic absorption; the peak plasma concentration occurs within 5–10 min [16], while sedation is observed within 15 min [5]. Clonidine may also reach supraspinal centres by cephalad migration through the CSF [17]. No excessive sedation was noticed in our patients after extradural administration of clonidine. Nevertheless, sedation induced by clonidine may occasionally induce snoring and hypoxaemia [18] and oral yohimbine easily reversed sedation in these individuals.

In the present study, clonidine-induced analgesia was also reversed partly by yohimbine, the effect being seen more on duration of analgesia, rather than its quality. Early VAS scores were comparable in those patients who received extradural clonidine and those who received extradural clonidine and oral yohimbine. However, the time from extradural injection of clonidine to supplementary analgesic demand was shorter in those patients given oral yohimbine. We speculate that, in the spinal cord, the ratio of concentrations between clonidine and yohimbine may have initially favoured clonidine, which rapidly crosses the dura mater after extradural administration. Later, this ratio may have changed, as systemic absorption of clonidine occurred and oral yohimbine reached the spinal cord alpha$_2$ receptors, shifting clonidine from its binding sites. Reversal of extradural clonidine-induced analgesia also depends on the respective doses of clonidine and yohimbine administered. In this study, the dose of yohimbine was determined from a previous open study in which yohimbine 16 mg seemed to be the minimal dose which reversed the sedation of clonidine 450 µg.

Hypotension and bradycardia related to extradural clonidine administration were not modified by oral yohimbine. The mechanism of the effect of clonidine on arterial pressure is complex. Clonidine produces hypotension by inhibition of the nucleus reticularis lateralis located in the ventrolateral medulla oblongata [19, 20]; it also directly inhibits sympathetic preganglionic neurones [21] and exerts a peripherally mediated vasoconstrictive effect [12]. The resultant action is a biphasic dose–response on arterial pressure, with a reduction at small doses partly corrected at large doses [2, 22]. In addition, several studies suggest that the supraspinal mechanism of action of clonidine on arterial pressure is mediated mainly by imidazoline receptors and not by alpha$_2$ adrenoceptors [22]. Indeed, intracisternal yohimbine has been reported not to reverse the hypotensive effect of clonidine or its inhibition of the nucleus reticularis lateralis [22]. Solomon, Brody and Gebhart have shown that the depressive effect produced by intrathecal clonidine in rats is prevented by a 10-fold greater dose of intrathecal yohimbine, but not altered by an equivalent dose of i.v. yohimbine [23]. A direct inhibition of sympathetic neurones may also play a role in the cardiovascular effect of spinally administered clonidine. This hypothesis is supported by the observation that hypotension is more marked after thoracic than lumbar extradural administration of clonidine in humans [24].

In conclusion, we found that sedation but not the haemodynamic effect of extradural clonidine was reversed by yohimbine in postoperative patients strengthening the hypothesis that the sedation is mediated by stimulation of supraspinal alpha$_2$ receptors. Yohimbine may be useful if excessive sedation leading to respiratory depression and hypoxaemia is observed in patients given clonidine for postoperative analgesia.

THE PRESSOR RESPONSE TO VENOUS CANNULATION: ATTENUATION BY PRIOR INFILTRATION WITH LOCAL ANAESTHETIC

B. T. LANGHAM AND D. A. HARRISON

SUMMARY

We have compared the cardiovascular response to insertion of an 18-gauge venous cannula in 40 healthy patients. In 20 of the patients, cannulation was preceded by infiltration of local anaesthetic. Both rate–pressure product and mean arterial pressure increased significantly ($P < 0.01$) compared with baseline when no local infiltration was used, but there was no significant change from baseline when infiltration with local anaesthetic preceded cannulation. We conclude that there is a significant pressor response to venous cannulation which is obtunded by prior infiltration with local anaesthetic. We recommend, therefore, that s.c. injection of lignocaine should be considered before insertion of an i.v. cannula, especially in the high risk patient. (Br. J. Anaesth. 1993; **70**: 519–521)

KEY WORDS

Anaesthetics, local: lignocaine. Complications: cardiovascular responses. Veins: cannulation.

Rate–pressure product (RPP) and mean arterial pressure (MAP) are important to the anaesthetist as accepted indicators of myocardial oxygen consumption [1] and intracranial pressure [2]. There has been a considerable amount of work performed attempting to minimize the increases in these variables associated with laryngoscopy and tracheal intubation [3]. These changes are especially important in high risk groups such as those with hypertension or increased intracranial pressure.

There have been no previous investigations on the effect of venous cannulation on RPP and MAP. Work in this department [4, 5] has already shown that the majority of anaesthetists do not use local anaesthetic before venous cannulation with small venous cannulae (18–22 gauge). We have shown also that patients find venous cannulation unpleasant and we could therefore formulate the hypothesis that venous cannulation would affect RPP and MAP. This study was undertaken to assess if such a response existed and if it could be attenuated by prior local anaesthetic infiltration.

PATIENTS AND METHODS

The study was approved by the Local Ethics Committee and written informed consent was obtained from all participants. We studied 40 adult patients undergoing minor elective surgical procedures under regional or general anaesthesia. Each patient was allocated randomly to one of two groups: group 1—venous cannulation with an 18-gauge Venflon; group 2—s.c. injection of 1% lignocaine 0.25 ml via a 25-gauge needle followed 1 min later by cannulation with an 18-gauge Venflon. Random allocation such that 20 patients entered each group was achieved by taking a pre-written card, blindly from a bag.

All patients were premedicated with temazepam 20 mg orally 1 h before surgery.

On arrival of the patient in the anaesthetic room, a Finapres non-invasive arterial pressure monitor (Ohmeda 2300) was placed on the middle finger of the patient's dominant hand. After a 5-min stabilization period, baseline recordings of heart rate, systolic pressure, diastolic pressure and MAP were obtained.

Cannulation or subcutaneous injection of local anaesthetic was then carried out by Investigator 1. The Finapres monitor and second investigator were separated from the patient and Investigator 1 by a screen. Readings were taken from the Finapres monitor by Investigator 2, who was unaware of the patient's group. Immediately upon cannulation or insertion of local anaesthetic, Investigator 1 informed the blinded Investigator 2 of time zero. Cardiovascular variables were recorded by Investigator 2 at times 0, 30 s, 1 min, 2 min and 3 min. In group 2, the local anaesthetic injection at time 0 was followed by cannulation 1 min later; Investigator 2 was unaware of this being performed. All cannulations were successful at the first attempt.

The baseline value for RPP was calculated for all patients, and the changes in RPP and MAP from the baseline at all subsequent time intervals were calculated. The results were analysed using Student's paired t test, Student's unpaired t test, Wilcoxon signed rank test, Mann–Whitney U test, analysis of variance or Kruskal–Wallis test where appropriate.

Present addresses:
*Department of Anaesthesia, Leicester Royal Infirmary, Leicester LE1 5WW.
†Department of Anaesthesia, Royal Hallamshire Hospital, Sheffield.

Statistical analysis was performed using SPSS/PC+4.0 on an Elonex 386S PC with DR DOS 6.0.

RESULTS

Forty patients were studied (14 male), aged 18–70 yr (mean 40 yr); age and gender were matched equally in the two groups. There were no significant differences between the groups in baseline readings of systolic pressure, diastolic pressure, mean arterial pressure or heart rate (table I).

The mean changes in MAP and RPP from baseline values are shown in figures 1 and 2. The changes in MAP from the baseline value at each time interval were analysed using Student's paired *t* test, and changes in RPP by the Wilcoxon signed rank test. In group 2 (local anaesthetic infiltration before cannulation), there was no significant difference from baseline for either MAP or RPP, either at the time of infiltration or subsequently on cannula insertion. In group 1 (cannulation alone), significant increases in MAP ($P < 0.01$) and in RPP ($P < 0.01$) occurred after cannulation. These increases were sustained for the following 3 min.

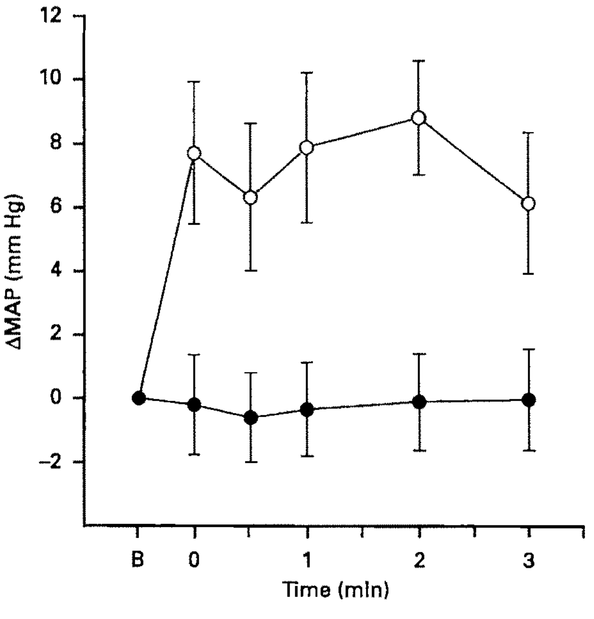

FIG. 1. Change in MAP from baseline (B) against time (mean, SEM). ○ = Group 1 (cannulation alone); ● = group 2 (s.c. injection of local anaesthetic followed at 1 min by cannulation). Time 0 = cannulation (group 1) or injection of local anaesthetic (group 2); time 1 min = cannulation in group 2.

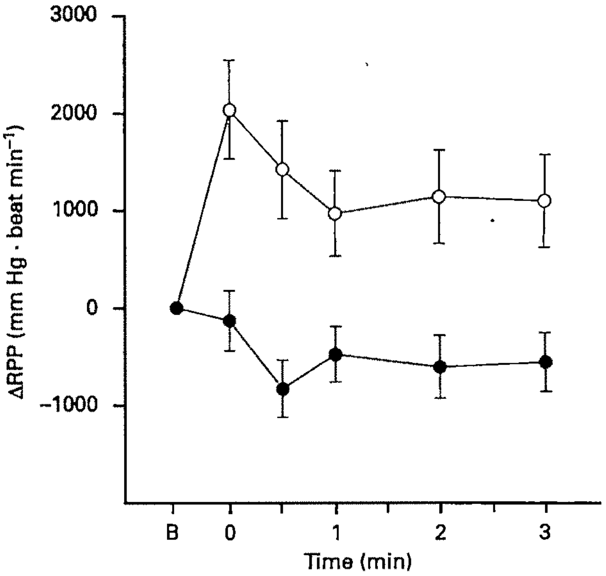

FIG. 2. Change in RPP from baseline (B) against time (mean, SEM). ○ = Group 1 (cannulation alone); ● = group 2 (s.c. injection of local anaesthetic followed after 1 min by cannulation). Time 0 = cannulation (group 1) or injection of local anaesthetic (group 2); time 1 min = cannulation in group 2.

The differences between groups in respect of MAP (Student's unpaired *t* test) and RPP (Mann–Whitney *U* test) were significant ($P < 0.01$) at each time during the study. Analysis of variance and the Kruskal–Wallis one-way ANOVA confirmed the effect of s.c. infiltration with lignocaine.

DISCUSSION

The Finapres is a non-invasive means of monitoring beat-to-beat variation in arterial pressure by means of a small inflatable finger cuff. The pressure in the cuff mimics digital artery pressure using a photoplethysmograph to determine flow cessation. It has been shown that the Finapres does not provide accurate between-patient measurements [6]; however, variability for within-patient measurements is acceptable. The Finapres is known to vary in its readings of MAP by as much as 20 mm Hg for up to 5 % of the time [7]. The MAP changes in our study group 1 were of the order of 10–15 mm Hg from baseline values; however, this change was sustained over a period of 3 min and did not occur in group 2. We conclude that the change observed in group 1 represents a true pressor response and cannot be attributed to inaccuracy of the Finapres.

We had shown previously [4, 5] that venous cannulation was unpleasant and painful and that these sensations were abolished by prior s.c. injection of local anaesthetic. The infiltration with local anaesthetic was found to be associated with minimal discomfort (median pain score of 1). From this work, we deduced that venous cannulation might affect RPP and MAP adversely and this has been confirmed by the results of the present study. We have shown also that the response to venous cannulation is abolished by the prior use of local anaesthetic infiltration, which suggests that the pressor response is not anticipatory in nature, but a reaction to the pain of cannulation.

Previous work has shown that changes in heart rate and the product of heart rate and systolic arterial pressure (RPP) reflect parallel changes in myocardial blood flow and myocardial oxygen consumption [8]. Gobel and colleagues [9] showed that RPP is the index which best correlates with myocardial oxygen consumption, and is therefore the critical one in defining the response of the coronary circulation to myocardial metabolic demand.

There is a large volume of published research on the pressor response to laryngoscopy and tracheal intubation during anaesthesia as these manoeuvres constitute a period of intense stimulation to the patient. The cardiovascular response may have adverse effects in patients with previously compromised coronary or cerebral circulation, and even healthy patients may suffer depression of left ventricular ejection fraction [10]. Many attempts have been made to obtund this response in high-risk patients using different agents and techniques, although no technique is associated with absolute cardiovascular stability. We have found a significant and sustained pressor response to venous cannulation in normotensive patients with a 10–15% increase in both MAP and RPP for at least 3 min. It would seem reasonable to expect there to be a proportionately greater response to this procedure in the hypertensive patient.

We conclude that s.c. local anaesthetic infiltration before venous cannulation should be a requirement in all patients, especially those deemed high risk, to maintain cardiovascular stability before other procedures are carried out.

SURFACTANT AND ADULT RESPIRATORY DISTRESS SYNDROME

W. JACOBSON, G. R. PARK, T. SAICH AND J. HOLCROFT

SUMMARY

In order to determine if the Adult Respiratory Distress Syndrome (ARDS) is associated with a shortage of pulmonary surfactant, we have examined a series of 155 undiluted tracheal aspirates obtained from 23 patients with ARDS and from 30 patients without ARDS, all 53 needing ventilatory support. The unfixed and unstained specimens were examined by polarized light microscopy for the presence of pulmonary surfactant. Free surfactant particles were present in the aspirates of 50 patients (95%). Within minutes of obtaining the specimen, in addition to showing surfactant, the examination of these undiluted, unfixed tracheal aspirates by light microscopy showed the presence of bacterial and fungal infection. As fibrinogen/fibrin inactivates surfactant, the undiluted aspirates of 21 patients with ARDS and of 30 patients without ARDS were stained for the presence of these proteins by a new slide method using 0.01 ml of tracheal aspirate. Fibrinogen/fibrin was found in the aspirates from 20 of 21 patients with ARDS and in only five of 30 patients without ARDS; these five had bronchopneumonia. The method has a sensitivity of 0.95 and a specificity of 0.83. The role of plasma proteins and of neutrophil leucocytes in causing ARDS is discussed. (Br. J. Anaesth. 1993; **70**: 522–526)

KEY WORDS

Lung: adult respiratory distress syndrome, surfactant.

It is still uncertain if the Adult Respiratory Distress Syndrome (ARDS) is caused by failure to make adequate amounts of pulmonary surfactant or if this substance is made in near normal amounts, but is inactivated by plasma proteins that have leaked into the alveolar lumina.

The purpose of this study was to establish the presence or absence of specific surfactant particles in undiluted tracheal aspirates of patients whose trachea was intubated, who needed ventilatory support and who either developed or had ARDS, in contrast with those who did not develop this complication. If there was no significant difference in the finding of surfactant particles between these two groups, this would lend support to the inactivation mechanisms. Fibrinogen/fibrin is known to inactivate pulmonary surfactant [1, 2].

Microscopic examination of undiluted, unstained tracheal aspirates in polarized light reveals the presence of the characteristic surfactant particles; examination in ordinary light may reveal the presence of large numbers of bacteria and fungi, thus showing the onset or presence of infection.

MATERIALS AND METHODS

Specimens of tracheal aspirate were obtained by inserting a sterile catheter approximately 3–4 cm beyond the end of the tracheal tube. No water or saline was used for this procedure, allowing undiluted secretions from the lower end of the trachea to be obtained. The aspirates were collected into a sputum trap (Bard, Crawley, U.K.) placed in a refrigerator at 3 °C to await transfer to the laboratory. This usually took less than 1 h. Specimens stored in this way have no changes in surfactant, cellular details or other features for at least 48 h. Specimens for microscopic examination were prepared by taking a sample of the aspirate from the sputum trap with a sterile loop, and placing it onto a microscope slide. No more than 10 µl was used. The specimen was covered immediately with a coverslip (22 × 22 mm, thickness grade 0), without any pressure. In order to prevent evaporation, the slides were stored at 3 °C in a small plastic box containing a strip of moist filter paper. Under these conditions, the slides could be re-examined 3 days later without significant changes having occurred in cells or surfactant particles, except that some spherical surfactant particles had undergone hydration and appeared now as ring-shaped liposomes.

Nearly all tracheal aspirates were examined by two observers (W.J. and T.S.) who were unaware of the clinical state of the patients. There was good agreement between the two observers—only three specimens needed re-assessment. A total of 155 tracheal aspirates from 53 unselected adult patients (ages 17–85 yr (median 62 yr); 28 male) was available. Table I shows the diagnoses on admission to the Intensive Care Unit and the patients who did or did not develop ARDS. There were 30 patients (17 male) who did not have ARDS and 23 (11 male) who had ARDS.

The clinical diagnosis of ARDS was made using the definition of Maunder and Hudson [3], based on

their previous paper [4]. The following five conditions were required for the diagnosis of ARDS: presence of respiratory distress, hypoxaemia, an increase in $F\mathrm{I}_{\mathrm{O}_2}$ failing to alleviate respiratory distress, generalized infiltrations of chest radiographs and exclusion of other cardiovascular or respiratory diseases.

Microscopic examination

Polarized light. The specimens were examined at a magnification of ×400 using a strong light source. Surfactant particles are birefringent and appear as bright spherical granules 0.5–3 μm in diameter, with a cross of polarization, against a black background. Most of the particles lie free in the secretion, but some may have been taken up by macrophages. It should be noted that the distribution of surfactant particles is usually uneven, as frequently they are in strands of secretion. Stable air bubbles, strongly birefringent (therefore lined by surfactant and remaining unchanged for 24 h), with a diameter ranging from less than 1 μm to about 30 μm, are also an indication of the presence of this substance.

Light microscopy. The unstained, wet preparation was examined with a narrow iris at magnifications of ×125 and ×400 to show cellular elements, micro-organisms (including fungal hyphae), haemosiderin (yellow brown), bile pigments (appearing as golden or green particles 1–3 μm in diameter) and aspirated matter, similar to milk fat droplets, refractile but not birefringent. For photographic records, phase contrast and darkfield illumination were used.

Stained specimens. Samples from all aspirates were spread on microscope slides. One slide was stained with Leishman's dye to make a permanent preparation of the cellular components and a second slide was stained with Grams's method, to record the presence of micro-organisms.

As ARDS is associated with increased permeability of capillary endothelial cells, staining procedures were developed for the presence of some plasma proteins in the tracheal aspirates. For this purpose, a droplet of secretion (not more than 10 μl) was spread on a slide over an area of 2 cm diameter. After drying in air, it was fixed immediately in 100% methanol for 2 min at room temperature, and dried in air again. The slides were then stained for fibrinogen/fibrin, immunoglobulin A (IgA) and albumin.

The fixed, air-dried specimen was placed in a Coplin jar with anti-human fibrinogen, developed in goat (Sigma F2.506), at a dilution of 1:1000 with tris saline buffer 0.05 mol litre^{-1} at pH 8.2 at 3 °C for 18 h. It was then washed twice, for 5 min in the buffer. The slide was then transferred to another Coplin jar containing anti-goat immunoglobulin (developed in rabbit)–alkaline phosphatase conjugate (adsorbed with human serum proteins, Sigma A4049) at a dilution of 1:1000 with tris saline buffer 0.05 mol litre^{-1} (pH 8.2) at 3 °C for 18 h. After two washes of 5 min in the buffer, the slide was placed in a freshly prepared solution of napthol AS/MX phosphate 2 mg, N, N- dimethylformamide 0.2 ml, tris saline buffer 0.05 mol litre^{-1} (pH 8.2) 9.8 ml, 20 μl of levamisole 1 mol litre^{-1}, Fast red TR salt 10 mg and 50 μl of magnesium chloride 1 mol litre^{-1}, and stained for 30 min at room temperature. (All chemicals from Sigma Chemical Company Ltd, Poole, Dorset, U.K.) The staining solution was filtered through Whatman No. 1 paper before use. The preparation was counterstained with 0.2% methyl green for 5 min, washed in running tap water for 5 min, then air-dried and mounted in DPX (BDH/Merck, Slaughter Ltd, Upminister, Essex U.K.).

A total of 120 slides was prepared by this method. The presence of fibrinogen/fibrin is shown in bright red colour. About 25 μg of fibrinogen/fibrin in 10 mg of wet aspirate appears bright red to the naked eye. Traces of fibrinogen/fibrin about 1 μg in the same volume appear as small red clumps or streaks under ×100 magnification, but in the absence of fibrinogen/fibrin the slides remain colourless. The optional counterstain with methyl green shows cell nuclei and glycoproteins of mucus in bright green colour. Staining for immunoglobulin A and albumin was with the corresponding antisera on separate slides.

The presence of surfactant in the tracheal aspirates was classified:

Abundant = most fields at ×400 magnification contained characteristic free surfactant particles.

Adequate = free particles were found in some, but not in other fields.

Few = an extensive search was required to detect any free particles.

None.

The presence of macrophages with ingested surplus surfactant particles was always considered an indication of adequate surfactant. The presence of strongly birefringent, stable air bubbles, even in the absence of free surfactant particles, was also taken as showing adequate surfactant. Owing to the uneven distribution of surfactant particles that were often entrapped in strands of mucus, more exact quantition was not feasible.

RESULTS

There was no difference in the occurrence of free surfactant particles in the tracheal aspirates of the 30 patients without ARDS and the 23 patients with

TABLE II. *Surfactant particles (and strongly birefringent air bubbles) in tracheal aspirates of patients (No. (%)) with and without ARDS. (For definition of terms see Materials and Methods)*

Surfactant particles	ARDS group ($n = 23$)	Non-ARDS group ($n = 30$)
Abundant	8 (35)	9 (30)
Adequate	12 (52)	16 (53)
Few	1 (4)	4 (13)
Only birefringent stable air bubbles	2 (9)	1 (3)
Total	23	30

ARDS (table II). This statement is based on the findings in 67 and 88 aspirates from these two groups, respectively. Chi-square analysis showed that for d.f. = 3, $P = 0.6$, thus confirming that there is no significant difference in the findings of free surfactant particles in the aspirates of patients with and without ARDS. In both groups, macrophages with ingested birefringent surfactant particles (with a cross of polarization) were a frequent finding.

The presence of fibrinogen/fibrin in the tracheal aspirates was strikingly different between the two groups. Whereas 25 of 30 patients without ARDS had no traces of these proteins in their 46 aspirates, 20 of 21 patients with ARDS did have these proteins present. The five patients without ARDS and with more than traces of fibrinogen/fibrin in their samples (four of them were weakly positive) had clinical and radiological evidence of bronchopneumonia. These five patients (of 30) must be considered "false" positive. There was one patient in the ARDS group of 21 whose four samples of tracheal aspirate showed only traces of fibrinogen/fibrin. He must be counted as a "false" negative. Thus the test for fibrinogen/fibrin to distinguish between ARDS and non-ARDS patients has a sensitivity of $20/21 = 0.95$, a specificity of $25/30 = 0.83$, with a predictive value of $45/51 = 0.88$.

Of the 21 patients with ARDS 14 (38 aspirates) stained positive for fibrinogen/fibrin in their first sample. Of these 14 patients, five were followed up until they recovered, when their aspirate became free from fibrinogen/fibrin. Another group of six patients whose 25 samples were negative at first when they did not have ARDS, subsequently tested positive when they developed the disease. Of this group of six patients, three were followed up until they recovered from ARDS, when their tracheal aspirates were free even from traces of fibrinogen/fibrin.

A large number of bacteria, together with numerous leucocytes, were found in the aspirates of 10 of the 30 patients without ARDS and in 11 of the 23 patients with ARDS, indicating infection. The presence of an occasional micro-organism was not considered to be clinically significant. Candida pseudohyphae surrounded by numerous leucocytes were seen in the aspirates of two patients without ARDS and in six patients with ARDS. The aspirate of one patient with ARDS contained aspergillus hyphae among numerous leucocytes. The presence of the occasional small group of candida or a single pseudohypha was not considered to be a sign of a fungal infection. It should also be noted that the presence of numerous neutrophil leucocytes without bacteria/hyphae in an aspirate is no indication of an infection.

DISCUSSION

This study of undiluted tracheal aspirates in polarized light is the easiest, quickest and cheapest method of establishing the presence of surfactant. Only a small amount of aspirate (not more than 0.01 ml) is needed. This simple technique allowed every aspirate to be evaluated for the presence of surfactant particles, however much contaminated by pus or blood, as the surfactant particles show up brightly against a dark background. Such contaminations render specimens unsuitable for biochemical analysis or surface tension measurements, which are the usual methods of measuring surfactant. The surfactant particles always remained separated, never agglutinated.

The two main findings of this investigation are the similar occurrence of free surfactant particles in the tracheal aspirates of 30 patients without ARDS and 23 with ARDS and the presence of fibrinogen/fibrin in the aspirates of only five of 30 patients without, but in 20 of 21 patients with ARDS.

In order to relate these two types of observations to the cause of ARDS, it has to be established that the 0.5–3 μm round, birefringent particles with a cross of polarization are surfactant particles. They are identical to those found in the type II cells of alveolar epithelium, the particles found in the lumen of the alveoli, in the tracheal aspirates of neonates and in the amniotic fluid after the 20th week of gestation. They have a large content of phosphatidylcholine and palmitate and can decrease surface tension to 10 mN m^{-1}. They are rare in the amniotic fluid of infants born with RDS and in the lungs of infants who died with RDS during the first 2 days after birth. Thus there is sufficient evidence that the characteristic particles represent an important form of surfactant [5–7]. It should be remembered that the surfactant particles in the aspirates were secreted into alveoli already coated with surfactant, thus representing surplus surfactant.

The presence of similar amounts of surfactant particles in 88 tracheal aspirates of 23 patients with ARDS and in 67 aspirates of 30 patients without the disease make it unlikely that ARDS is caused primarily by a shortage of pulmonary surfactant. In view of the known capacity of fibrinogen/fibrin to inactivate surfactant [1, 2], and described by Ashbaugh and his colleagues [8] in ARDS, it is most likely that these proteins have interfered with the function of surfactant, as they were found in 20 of 21 patients with ARDS and only in five of 30 patients without ARDS, all five having bronchopneumonia. The appearance of fibrinogen/fibrin in the aspirates correlated with the onset of ARDS in the six patients in whom aspirates were available before they developed ARDS. Conversely, these proteins disappeared from the tracheal aspirates in the eight patients who recovered from ARDS.

The inactivation of pulmonary surfactant by fibrinogen/fibrin and other plasma proteins has been

TABLE III. *Phospholipid values per ml of lavage fluid as reported by Pison and colleagues [7] and as calculated from the data of Gregory and colleagues [6] (see Appendix).* n = *No. samples*

	Phospholipid (μg ml^{-1})	
	Gregory	Pison
Normal	15.0 ($n = 29$)	84.1 ($n = 29$)
"At risk" or low score ARDS	11.0 ($n = 20$)	65.7 ($n = 77$)
ARDS	5.4 ($n = 66$)	65.1 ($n = 58$)

studied extensively [1, 2, 8–14]. A faulty synthesis of the surfactant lipid as a cause of ARDS has not been detected. The physical subtypes of surfactant are not caused by a change in lipid synthesis [15].

The question if inactivation of surfactant by plasma proteins, inadequate synthesis of it, or both, causes ARDS has been examined by two groups who came to opposite conclusions: Gregory and colleagues [16] found a 45 % reduction in phospholipids in lavage fluid of patients with ARDS compared with an "at risk" group and also a reduction by 67 % compared with the lavage fluid of normal persons. Conversely, Pison and colleagues [17] found no difference in the content of the lavage fluid of ARDS and non-ARDS patients. Gregory's group reported their findings as µmol of phospholipid in the reconstituted high-speed pellet of the lavage fluid, while Pison's group reported their findings as phospholipid µg/ml lavage fluid. In order to compare their respective findings, the former values must be converted to the latter. The calculations are given in the Appendix. Table III shows Pison's much greater values of phospholipid extracted from lavage fluid of the three groups (normal, non-ARDS and ARDS patients) and that there is no difference in the amount of phospholipid found in the lavage fluid of the two groups of patients. Our own observations on tracheal aspirates (not lavage fluid), using polarized light microscopy, are in agreement with those of Pison's group.

The problem of inactivation of pulmonary surfactant is a complex one, as other plasma proteins such as albumin and IgA can interfere with its function. Furthermore, the surfactant proteins SP-A, SP-B and SP-C can protect the lipid from inactivation by plasma proteins [18–23].

The leakage of plasma proteins into the alveoli is caused by damage of the alveolar endothelial cells. One of the factors contributing to this damage is that activated neutrophils stick to the endothelium and emigrate into the air spaces. They produce toxic oxygen radicals [24–32] which can also affect the endothelium [33, 34]. Although artificial surfactant may bring temporary relief [35], it does not prevent the capillary damage. Prevention of capillary damage by means of specific inhibitors of enzymes in neutrophils, which produce toxic oxygen radicals that in turn damage the blood–air barrier, would be a promising target for therapeutic research.

The presence of large numbers of white blood cells (WBC) in the aspirates, mainly neutrophils and macrophages/monocytes, is no indication of an infection [36]; damaged lung parenchyma may have induced the emigration of WBC. A clinically important infection was diagnosed only when the aspirate contained numerous micro-organisms with numerous WBC (except in a leukopenic patient). The high incidence of infections among the ARDS patients (78 %) compared to the non-ARDS group (43 %) is in agreement with others [37].

It is likely that inactivation of surfactant by plasma proteins is important in the development of ARDS. However, later in the disease process, when hyaline membranes coat increasing areas—indicating loss of epithelial cells in the alveoli and respiratory bronchioles—production of surfactant may be reduced.

APPENDIX

To convert the values of Gregory and colleagues [16] of phospholipid µmol/ml reconstituted high speed pellet into phospholipid µg/ml lavage fluid as reported by Pison and colleagues [17] (see table III):

(1) Gregory's group used saline 3 × 50 ml for lavage; Pison's group used saline 5 × 20 ml.

(2) Recovery of lavage fluid by Gregory's group for normal control was 95 ml, for "at risk" patients 56 ml, for ARDS patients 83 ml. Pison's group recovered 60–70 ml for all three groups.

(3) Gregory's group reconstituted the high speed pellet for measurement of phospholipid with 0.2 ml saline. As they report the amount of phospholipid in µmol/ml reconstituted pellet, their figures must be divided by 5 to obtain the actual amount of phospholipid extracted from the high speed pellet.

Normal group. Phospholipid 7.99 µmol/ml reconstituted pellet divided by 5 = phospholipid 1.6 µmol in 85 ml of lavage fluid (from 95 ml recovered, some was taken for cell counts, cytology and bacteriology); thus phospholipid 0.019 µmol/ml lavage fluid. To convert phospholipid µmol into µg, multiply by 775, assuming an average molecular weight of various phospholipids as 775 (some authors assume 750; we chose the greater value to give advantage to Gregory's group). Thus 1 ml of lavage fluid of normal subjects contained phospholipid 15 µg/ml lavage fluid.

"At risk group". Phospholipid 3.38 µmol/ml reconstituted pellet converts to phospholipid 11 µg/ml lavage fluid (assuming a 50-ml volume of phospholipid PL). They recovered 56 ml minus deductions (see above).

ARDS group. Phospholipid 2.47 µmol/ml reconstituted pellet converts to phospholipid 5 µg/ml lavage fluid (assuming a 75-ml volume, they recovered 83 ml minus deductions).

(Summarized in table III.)

PENETRATION OF AN AEROSOL, PRODUCED BY FILM ATOMIZATION, THROUGH THE CARINAL BIFURCATION

T. J. J. INGLIS, J. G. JONES AND S. PAXTON

SUMMARY

We have measured the size of spots produced by atomization of simulated biofilm particles from a tracheal tube. Draughtsman's ink was atomized from 8.5-mm i.d. Portex tracheal tubes, using an airflow of 1 litre s^{-1}, and trapped on vertical acetate sheets. The spots produced by these particles were compared with the spot size after entrainment and dissemination from an ink-lined tracheal tube through a bifurcating tracheobronchial tube towards a glass plate. Spot dimensions were measured by computer-assisted image analysis of a video image. The smallest particles observed on the acetate sheets were 4–17 µm in size. In the bifurcating tube experiment, large particles were deposited around the carinal bifurcation, but smaller particles traversed the bend. The smallest spot size observed (7 µm minimum; 17 µm median) corresponds to particles small enough to penetrate further into the lower respiratory tract. Travel via a tube similar to the carinal bifurcation suggests that fragments of biofilm entrained in the tracheal tube could be propelled deeper into the respiratory tract during the inspiratory phase of mechanical ventilation. (Br. J. Anaesth. 1993; **70**: 527–531)

KEY WORDS

Airway: aerosol penetration. Equipment: tracheal tube.

Critically ill patients are at increased risk of nosocomial pneumonia. Although pneumonia in patients undergoing artificial ventilation is often attributed to bacteria from endogenous flora, the mechanism by which these organisms are finally disseminated into the lungs has not been defined. It has been suggested that the material lining the inner surface of the tracheal tube ("tracheal tube biofilm") can be dislodged and carried further into the lung during suction catheter movement [1]. More recently, it was shown that the gas–liquid interaction between airflow along the tracheal tube and biofilm lining the tube could dislodge bacteria from the biofilm and scatter this material over a range of many centimetres [2]. That study did not explore the likelihood of dissemination through a branched tube system such as the trachea and bronchi. In the present study, biofilm dissemination from the tracheal tube was simulated to determine the size of the smallest particles produced and to examine if they would traverse a Y junction constructed to the dimensions of the trachea and main bronchi.

MATERIALS AND METHODS

Atomization

Particle atomization produced by an interaction between gas flowing through a liquid lining the tracheal tube was studied in the following manner. A preweighed Portex tracheal tube of 8.5-mm i.d. was straightened and pointed horizontally towards a vertical acetate sheet held at 32 cm from the tip of the tube. A 1.0-ml bolus of draughtsman's ink (Rotring GmbH, Germany) was placed in the distal 3 cm of tube, and allowed to pool along the tube. A ventilator (Erica, Engstrom, Denmark) was connected to the tracheal tube connector using standard ventilator tubing and run for a single cycle to give a flow rate of 1 litre s^{-1} (i.e. a tidal volume of 1 litre in 1 s) measured with a Fleisch II pneumotachograph. The acetate sheet was removed immediately and air dried while held at room temperature in a horizontal position. This procedure was repeated nine times under identical conditions, using a fresh tracheal tube each time. After each experiment, the tube was sealed with paraffin film to contain the remaining liquid during transport and reweighed after removal of the film to calculate the mass of liquid entrained.

A further series of experiments was carried out when particles entrained from the tracheal tube were directed via a horizontal bifurcating tube towards a vertical sheet of 2-mm picture glass. The bifurcating tube used in the procedure was constructed to the dimensions of the trachea and main bronchi as described by Weibel [3]. The bifurcating tube was designed and constructed in the workshops of the Royal Aircraft Establishment, Farnborough, and had a constant cross sectional area between "tracheal" and "bronchial" levels. The Portex tracheal tube was held horizontally and placed in the "tracheal" part of the bifurcating tube, after which the cuff was inflated to seal the tube in the model trachea. The glass sheet was placed perpendicular to the direction of flow, 2.5 cm from the distal end of each bifurcation (the total distance between tracheal

tube tip and glass being 32 cm), and inspiratory flow was simulated by running the ventilator for a single cycle. The same ink volume, loading technique, ventilator and cycle were used in this experiment as described above. The experiment was repeated without the intervening Y-piece, and a fresh glass sheet held at 32 cm from the tracheal tube tip.

Image analysis

The nine acetate sheets were examined initially by light microscope (magnification × 400, with graticule eyepiece) to obtain an estimate of the range of spot sizes. To avoid losing spot images as a result of buckling or detachment from the acetate sheets, the sheets were photographed with 35-mm black-and-white film. The negatives were then digitized using the CCTV camera and a dissecting microscope (Wild, Heerbrugg, Switzerland) and scanned in a single straight line from the area of most dense particle deposition at the centre of the scatter pattern to its furthest edge. The smallest spots were selected visually from the video screen and at least four possible spots were measured from each pattern. Total object number, total object area, mean object area and the *D* value (diameter of a circle of area identical to that of the scanned image of each spot) were obtained using the image analyser. Pixel dimensions were 0.6 × 1.1 μm. The software used was Vidi-pp version 1.0 (ULIS, Leeds) running under DOS 4.01 on an IBM-compatible microcomputer (Elonex PC 486B/25) with a framegrabber (ROMBO, Livingstone, Scotland), a CCTV monochrome camera (Hitachi, U.K.), and a photomicroscope (photomicroscope model II, Zeiss, Germany).

Glass sheets were used in the Y-tube procedure to avoid problems with buckling and loss of ink spots during microscopy. Glass was also used to reduce any electrostatic repulsion of smaller particles by the surface on which impaction would occur. Spots produced by particles passing through the bifurcating tube were deposited in a broad crescent-shaped area. A 2.5 × 2.5-mm square was chosen for image analysis in the wider part of the crescent, avoiding the larger spots, as these were large enough to obscure several smaller ones. This area was marked on the plate and subjected to image analysis, as above.

RESULTS

Extensive entrainment of liquid lining the tube resulted in extensive scatter of ink spots each time the experiment was repeated, although there was some variation in the quantity of material deposited on the acetate sheets (fig. 1, table I).

In the bifurcating airway experiment, most spots large enough to be seen easily with the naked eye were deposited on the Y-tube wall at the bifurcation (fig. 2). Nevertheless, a collection of smaller spots was obtained on the glass plates positioned opposite the "bronchial" branches of the Y-tube. Most of these particles could not be seen easily without magnification. When their distribution was com-

DISCUSSION

Particle deposition in the lungs of spontaneously ventilating subjects has been investigated previously [4] and two-phase gas–liquid flow recognized as a mechanism for mucus transport in the airways of patients with increased thickness of the mucus layer [5]. There is some indirect evidence that two-phase gas–liquid flow occurs commonly in tracheal tubes containing a luminal biofilm [6], but the atomization and trajectory of biofilm particles in patients undergoing mechanical ventilation has not yet received detailed attention. An indwelling tracheal tube may increase substantially the likelihood of propulsion of atomized tracheal tube biofilm into the lungs, by bypassing the inertial impaction filter system of the upper respiratory tract in these patients.

This simulation study suggests that low viscosity biofilm particles small enough to reach far into the lung can be disseminated with a velocity sufficient to

traverse the first order bifurcation in a model of an intubated trachea with symmetrically branched main "bronchi". The size of spots obtained in this series of experiments may overestimate particle size, because there may be some degree of particle spread at the moment of impact. A study of deposition of nebulized aerosols in spontaneously breathing volunteers found that 44% nebulizer contents reached the lungs when the particle size was 10.3 μm mass median diameter [7]. In this study, percentage deposition increased with decreasing aerosol particle size. In another radiolabelled particle deposition study, particles of 0.5–2 μm (approximately the size of single bacterial cells) were found to reach the alveoli without significant loss, whereas particles > 12 μm were not able to penetrate the alveoli [8]. The various equations used to predict particle deposition in the Weibel morphological model of the human lung have been applied to inhalation of particles in the 5-μm range [9], which would be expected to result in maximum deposition at the segmental and subsegmental bronchial level. If these results can be applied to particles entrained from tracheal tube biofilm, the majority would not be expected to penetrate further than this level; however, altered gas flow pathway and pattern expected during mechanical ventilation may alter substantially particle deposition.

The process by which particles are produced in the tube can be described as gas–liquid interaction, in which the degree of interaction is sufficient to cause fracture of a gas–liquid interface (the luminal biofilm surface) with onward propulsion of liquid particles by the gas phase. Physical factors governing gas–liquid interaction in tubes with a liquid lining have been determined previously, and it was shown that the minimum thickness of liquid lining layer required for gas–liquid interaction was 0.5 mm [10]. The critical flow required to generate gas–liquid interaction in an 8.5-mm i.d. tube with a 0.5-mm liquid lining layer is equivalent to a Reynolds number of > 4000. A Reynolds number of 2000, synonymous with turbulent flow, is achieved readily in a tube of this size during mechanical ventilation, and at a flow of 1 litre s^{-1} the Reynolds number is more than 7000. This greater Reynolds number indicates a greater energy loss through gas–liquid interaction, with fluid expulsion from the tracheal tube and the production of mist or particle flow [11].

An important determinant of particle entrainment is the viscosity of the lining liquid. In clinical practice, tracheal tube biofilm is a heterogenous matrix and a wide range of liquid viscosity would be expected in a single biofilm. The biofilm layer adjacent to the luminal surface and therefore most subject to fragmentation is also likely to be the least viscous, because of factors such as condensation of humidifier water and the instillation of saline during tracheal suction procedures. The simulation experiments described in the present study were conducted therefore with a liquid of viscosity similar to that of water. More viscous biofilms are less likely to undergo fragmentation under the same conditions.

Our results provide evidence to suggest that gas–liquid interaction in the tracheal tube provides an effective means of disseminating particles into the ventilated lung. Further work on particle entrainment and scatter from tracheal tube biofilm under different conditions of gas flow is required. The dissemination of bacteria and other components of tracheal tube biofilm as a result of physical processes occurring in the tracheal tube requires consideration as a possible step in the pathogenesis of nosocomial pneumonia.

EFFECT OF HYPEROXIA ON THE BREATHING OF PATIENTS ANAESTHETIZED WITH INFUSIONS OF PROPOFOL

A. C. DOW AND N. W. GOODMAN

SUMMARY

We have assessed the effects on the pattern of breathing of changing the inspired gas from air to oxygen, by analysing the 15 breaths before and 15 breaths after the change, in 10 patients anaesthetized with propofol. Eight of 14 changes decreased tidal volume ($P < 0.01$) by between 16% and 30%. Nine changes increased ventilatory cycle time ($P < 0.01$) by between 8% and 16%. Total ventilation decreased by between 7% and 33%. The peripheral chemoreceptors are active during propofol anaesthesia, and patients should be able to respond to hypoxia. (Br. J. Anaesth. 1993; **70**: 532–535)

KEY WORDS

Anaesthetics, intravenous: propofol. Ventilation: peripheral chemoreflexes, spontaneous ventilation.

Beddoes suggested to Davy that general anaesthesia depressed respiration; he had noted the "purplish colour of blood flowing from the leeches" that had been placed on patients breathing nitrous oxide [1]. In general, volatile and i.v. anaesthetic agents reduce the ventilatory sensitivity to carbon dioxide; this has been tested usually during hyperoxia, when the sensitivity is mainly of the central chemoreceptors. The response of the peripheral chemoreceptors to hypoxia is depressed by halothane anaesthesia [2], and the peripheral hypoxic response may be more sensitive to general anaesthesia than the central response to carbon dioxide. This discharge of the peripheral chemoreceptors in hypoxia is reduced by propofol anaesthesia in animals [3]; the investigators commented that even "an i.v. dose... smaller than the standard induction dose caused a visible depression of activity in normoxia". Earlier, Duffin, Triscott and Whitwam had studied the ventilatory response to two breaths of 100% oxygen in patients anaesthetized with either halothane or thiopentone [4]. This was applying Dejours' idea [5] that the initial response to hyperoxia is mediated entirely by the chemoreceptors, before there is time for any secondary responses. Five of Duffin's seven patients who received thiopentone had a 10% reduction in total ventilation, occurring about six breaths after the two breaths of oxygen. The patients who received halothane had a smaller, non-significant, reduction in total ventilation. Knill, Bright and Manninen studied the effects of thiopentone [6]: the hypoxic response was unaffected, but the response to carbon dioxide reduced. We have investigated the effect of altering the inspired oxygen concentration on the breathing pattern of patients anaesthetized with propofol.

PATIENTS AND METHODS

Twelve patients gave written informed consent to take part in a continuing study of breathing patterns under anaesthesia, which had been approved by the local Research Ethics Committee. All patients were non-obese, ASA I and with airways judged before operation to be easy to manage. Six patients accepted the offer of premedication with a benzodiazepine.

When the patient arrived in the anaesthetic room, an oximeter probe was placed on the finger and an arterial pressure cuff on the arm. The cuff was not used routinely because of the disturbing influence of cuff inflation on the breathing. Belts for respiratory inductance plethysmography were fitted around the ribcage and abdomen, and the signal was calibrated (see below) before induction of anaesthesia. A 20-gauge cannula was inserted into a vein in the non-dominant arm, and was connected to a propofol infusion. An induction dose of 2–3 mg kg^{-1} was given, and supplementary doses of 20–40 mg if necessary to allow insertion of a laryngeal mask airway. The patient breathed air via a Mapleson A system, with a fresh gas flow of at least 10 litre min^{-1}. Anaesthesia was maintained with a reducing infusion of propofol: 13 mg kg^{-1} h^{-1} for 10 min, 11 mg kg^{-1} h^{-1} for 10 min and finally 9 mg kg^{-1} h^{-1}. In some patients it was necessary to maintain the infusion at a given rate for longer than 10 min. Oxygen was added to the fresh gas flow if the saturation was 90% or less.

A sampling tube for capnography was placed in the right-angle connector of the laryngeal mask airway. Outputs from the capnograph and pulse oximeter were recorded onto the two-channel recorder of the capnograph (Gould Godart Mark III). The respiratory inductance plethysmograph (Respitrace model 10.9000) was calibrated before induction of anaesthesia by double least squares linear regression against a pneumotachograph (Fleisch head: Godart pneumotachograph 17212), itself calibrated

ALASDAIR C. DOW, M.B., CH.B., M.R.C.P. (U.K.), F.R.C.ANAES.; NEVILLE W. GOODMAN, M.A., D.PHIL., B.M., B.CH., F.R.C.ANAES.; University Department of Anaesthesia, Medical School Unit, Southmead Hospital, Bristol BS10 5NB. Accepted for Publication: December 15, 1992.

against a 1-litre syringe. The calibration and subsequent analysis were by computer program (BBC B+/Macintosh IIsi running BBC Basic), as reported previously [7]. The inductance plethysmograph was not recalibrated after induction of anaesthesia, but patients were not moved after induction and we were interested, not in absolute values of tidal volume, but only in changes occurring when stimuli were applied in periods of otherwise stable breathing. Signals from the Respitrace, and of capnography from the later patients, were recorded by frequency-modulated tape recorder (Racal Thermionic Store 4).

When there was clinically stable anaesthesia, with no change in the infusion rate over the preceding 100 breaths, the fresh gas flow was changed to 100% oxygen. If time allowed, some of the patients were later exposed again to air, and again to oxygen.

At the end of the study, the inductance belts were removed and the patients were taken into the operating theatre for their scheduled surgery.

Analysis

The maximal reduction in total ventilation after two breaths of oxygen in Duffin's study occurred about six breaths after adjustment of the inspired gas [4]. We therefore ignored six breaths, starting with the breath on which the gas flow was adjusted. We analysed two groups of breaths: the 15 breaths before the change to oxygen, to establish a baseline, and the 15 breaths *after the gap* of six breaths.

Data were transferred to a Macintosh IIsi computer (BBC Basic, FileMac: Human Computer Interface Ltd). Programs written in BBC Basic, running on the Macintosh, were used to prepare text (ASCII) files used as input to a statistical package (StatView SE+Graphics: Abacus Concepts) and a spreadsheet (Excel V3.0: Microsoft).

We analysed tidal volume and ventilatory cycle time formally, and present means and 95% confidence limits on those means. Total ventilation was calculated from tidal volume and cycle time; only the means are presented.

RESULTS

One patient remained apnoeic for 15 min after induction of anaesthesia, despite an end-tidal carbon dioxide that reached 7.1%; the study was abandoned. Another patient coughed and developed laryngospasm after induction, and required tracheal intubation. A total of 14 changes was obtained from the other 10 patients.

Acute hyperoxia reduced the tidal volume by up to 30% (table I). Ventilatory cycle time increased by up to 16% (table II); this was caused by prolongation of expiratory time (values not given). Effects on tidal volume and cycle time varied between patients, but total ventilation was reduced in all patients, by between 7% and 33% (table III).

The five records with the greatest changes in total ventilation are shown individually in figure 1 and, to show the time course of the response, are summed in figure 2. The change in total ventilation was maximal by the 11th breath (about 30 s) after the change of

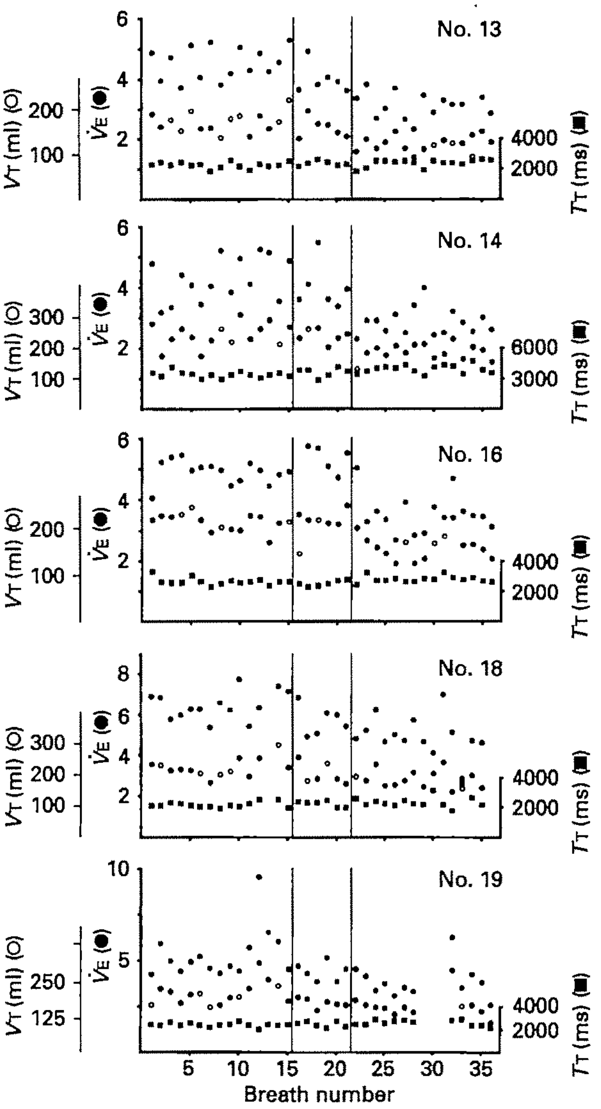

FIG. 1. Tidal volume (V_T: ○), total ventilation ($\dot{V}_E$: ●) (units, omitted for clarity: litre min^{-1}) and ventilatory cycle time (T_T: ■) at the five largest changes in ventilation caused by hyperoxia in patients anaesthetized with an infusion of propofol. The first vertical line indicates when the fresh gas was changed from air to 100% oxygen; the second vertical line marks the start of the 15 breaths used for comparison with the baseline breathing air. Patient number top right. Note that some invalid breaths caused by transient arm movements were deleted: 13 and 36 from patient No. 18; 29–31 from patient No. 19.

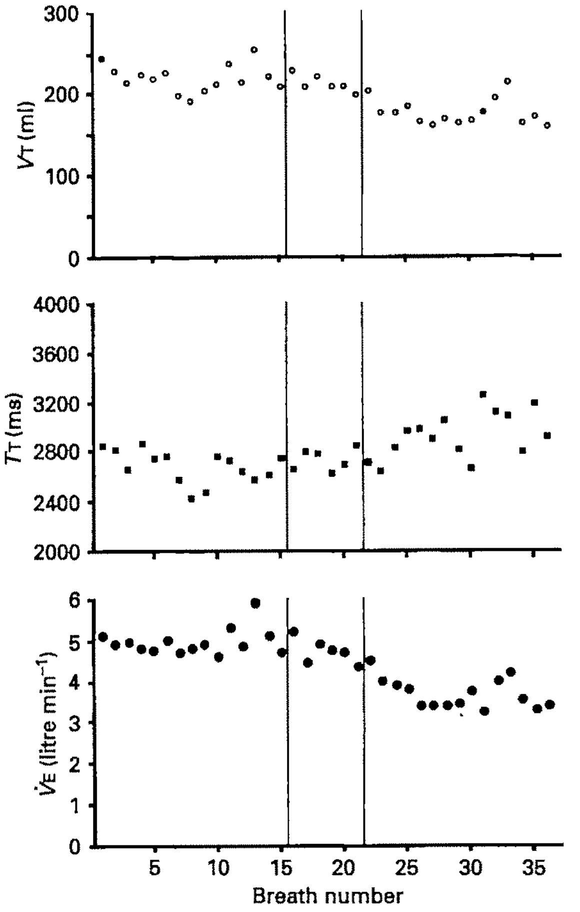

FIG. 2. Mean values for tidal volume (V_T: ○), ventilatory cycle time (T_T: ■) and total ventilation ($\dot{V}_E$: ●) calculated from the five largest changes in ventilation caused by hyperoxia in patients anaesthetized with an infusion of propofol. The first vertical line indicates when the fresh gas was changed from air to 100% oxygen; the second vertical line marks the start of the 15 breaths used for comparison with the baseline breathing air.

gas mixture. The decrease in tidal volume in these summed responses occurred before the increase in cycle time.

DISCUSSION

The ventilatory response to hyperoxia in normal awake humans is complex. The increased arterial partial pressure of oxygen is a mild depressant. At least when applied as a sudden stimulus in awake humans [5], the initial depression of ventilation occurs within a few breaths but, in continuing hyperoxia, the reduced ventilation leads to an increased partial pressure of carbon dioxide, which counters the depression. Hyperoxia and hypercapnia have opposing effects on cerebral vasodilatation [8]. This affects the relation between the arterial carbon dioxide and its partial pressure at the central receptors. It is not just the magnitude of these various effects that is complicated, but the time courses in addition—both of the vascular responses and of the ventilatory ones; the central chemoreceptors, almost entirely responsible for the secondary response to hypercapnia in hyperoxia, react more slowly than the peripheral chemoreceptors [9].

We did not attempt to maintain isocapnia, and a small increase in end-tidal carbon dioxide accompanied many of the changes to breathing oxygen. In some patients, the end-tidal carbon dioxide decreased but became irregular, which was probably an indication that end-tidal gas was not alveolar; there is no reason why arterial carbon dioxide should not have increased with every decrease in ventilation.

Of itself, the change in carbon dioxide should oppose the ventilatory effects of hyperoxia, so does not affect the conclusion that patients anaesthetized with propofol can respond to changes in the partial pressure of oxygen. The response to hyperoxia was rapid: for the five largest responses, the mean tidal volume was already less than any baseline breath by the seventh breath after changing the gas mixture. Increases in cycle time lagged a couple of breaths behind the decreases in tidal volume. The response in resting awake man occurs "after a delay of 10 seconds" [5]. The response in patients anaesthetized with propofol is probably little different, given our unknown delay between changing the gas mixture and the onset of hyperoxia; it take a few seconds for changes of the flowmeter settings to affect the oxygen concentration of the inspired gas.

We did not analyse the ventilation beyond 15 breaths because of the later unpredictable effects. For the same reason, we did not analyse formally the ventilatory effect of switching back from oxygen to air; the partial pressure of oxygen then changes too slowly to have the sudden and unequivocal effect on ventilation of the change from air to oxygen. Fifteen breaths is about 30–50 s at the breathing frequencies of our patients, and secondary effects of hyperoxia would have started in this time. In retrospect, we would have reported much the same findings if we had measured only five breaths after noticing an effect. Part of the problem of analysis was, again, the unknown delay after altering the flowmeters; some patients may have started to respond during the six ignored breaths.

No analysed change of gas mixture was made within 100 breaths (about 4–7 min) of changing the rate of infusion of propofol. We cannot state that anaesthesia was "steady-state", only that the infusion was constant, but depth of anaesthesia should have been stable enough not to confound ventilatory changes measured over 1–2 min around a change of gas mixture. We used only clinical criteria to assess depth of anaesthesia (pattern of ventilation, size of pupils, movement of limbs). The response to hyperoxia may be affected by depth of anaesthesia, but we did not measure plasma concentrations of propofol, so can make no comment. We do not believe that predictions of plasma concentration made from rate of infusion are precise enough in individual patients, and we would not presume that we can correlate our clinical assessments of depth with our patients' responses to hyperoxia.

We conclude from our data and the earlier work of Duffin, Triscott and Whitwam [4] that the early response to hyperoxia was caused by alteration of peripheral chemoreceptor firing. Some reduction in total ventilation occurred at all changes, but the important component of the change was sometimes the decrease in tidal volume and sometimes the increase in cycle time. For only one change (the second change in patient 20) did neither variable alter at the 1% level. Differences in response could have occurred because of differing anaesthetic depth at the changes or differing arterial partial pressures of oxygen in the patients before the hyperoxia [5], but the response to hypoxia varies between individuals. Two of Duffin's seven patients given thiopentone did not respond to hyperoxia [4].

The alterations in both tidal volume (reflecting decreased ventilatory drive) and cycle time (caused by longer expiratory time) are typical of transient chemical stimuli affecting the peripheral chemoreceptors [10]. When the stimulus is mainly of the central chemoreceptors, for instance during hyperoxic rebreathing of carbon dioxide [9], the increase in ventilation is almost entirely because of increased drive [10], certainly in patients anaesthetized with propofol [11].

Ponte and Sadler studied the effect of propofol on the carotid body chemoreceptors of cats and rabbits [3], and observed that an infusion of propofol into the carotid artery abolished chemoreceptor discharge in normoxia and prevented the increase in discharge that occurs in hypoxia. Thiopentone and etomidate did not abolish the response to hypoxia. Their propofol infusion of 1.5–3 mg min^{-1} (90–180 mg h^{-1}) is equivalent to 18–36 mg kg^{-1} h^{-1} (if the animal weight is assumed to be 5 kg), which is a greater rate than that used in the present study. Species differences may also be important.

We suggest that the peripheral chemoreceptors are active during clinical anaesthesia with propofol, and that at least some patients may be able to respond to hypoxia.

EFFECTS OF ACTIVE AND PASSIVE SIGHS IN NORMOXIA AND HYPEROXIA ON THE BREATHING OF PATIENTS ANAESTHETIZED WITH INFUSIONS OF PROPOFOL

N. W. GOODMAN AND A. C. DOW

SUMMARY

Spontaneous augmented breaths (active sighs) reduced the tidal volume and inspiratory time of succeeding breaths; manual lung inflations (passive sighs) reduced the tidal volume but had little effect on inspiratory time. Sighs in air, whether active or passive, reduced tidal volume more than sighs in hyperoxia (100% oxygen or 33% oxygen in nitrous oxide) after both active and passive sighs (overall difference about 10%); the reduction in inspiratory time after a sigh was less affected by gas mixture. Calculated mean inspiratory flow was reduced after passive sighs, but active sighs were more likely to cause arousal, which complicated the analysis. Tidal volume was reduced after a sigh partly because of reduced peripheral chemoreceptor input, the main effect of which was to reduce inspiratory flow, and partly because inspiratory time was shorter. Although the chemoreceptors may affect inspiratory time after a sigh, the greater effect of active sighs compared with passive sighs makes it likely that the shortening was either part of the neural output that causes spontaneous sighs, or was caused by mechanoreceptor input not mimicked by manual lung inflation. (Br. J. Anaesth. 1993; **70**: 536–541)

KEY WORDS

Anaesthetics, intravenous: propofol. Ventilation: spontaneous sighing, manual lung inflation, peripheral chemoreflexes.

Spontaneous sighs, or augmented breaths [1], transiently change the pattern of breathing. In patients anaesthetized with propofol, the succeeding breaths have shorter inspiratory times and reduced mean inspiratory flows [2], so their tidal volumes are smaller. These changes last about 10 to 20 breaths after the sigh. A sigh causes a transient alteration in the arterial partial pressures of carbon dioxide and oxygen, and these alterations are at least partly the cause of the altered breathing pattern. Khoo and Marmarelis [3] suggested using the response to a sigh to measure the gain of the peripheral chemoreflex. We have investigated the causes of the altered pattern by comparing the effects of spontaneous sighs, which we refer to as "active sighs", with the effects of manual inflations of the lungs, "passive sighs", in patients anaesthetized with propofol and breathing air or hyperoxic mixtures. Our hypothesis was that a sigh in hyperoxia would cause less disturbance than a sigh in air because of reduced peripheral chemoreceptor input; and that from the comparison between active and passive sighs we could show how much of the disturbance was caused by the change in chemical stimulus and how much by other factors.

A preliminary report has been made of this work [4]. Analysis of the effects of hyperoxia on the undisturbed pattern of breathing will be presented separately.

PATIENTS AND METHODS

Patients of slim build and with what we considered easily manageable airways were asked for their consent. We studied 19 patients (16 women), all ASA I, aged 23–52 yr and weighing 49–83 kg. Patients were prescribed a benzodiazepine for premedication if they wished ($n = 9$).

A venous cannula was placed in the non-dominant arm. A probe for pulse oximetry and a cuff for a non-invasive monitor of arterial pressure were attached. We did not intend to measure arterial pressure unless we were unhappy with the clinical condition of the patient, because of the inevitable disturbance to the breathing caused by arousal when the cuff inflates. Anaesthesia was induced with propofol and a laryngeal mask airway was inserted. Anaesthesia was maintained by a three-step reducing infusion starting at 13 mg kg^{-1} h^{-1}, stepping after 10-min intervals to 11 mg kg^{-1} h^{-1}, and then to 9 mg kg^{-1} h^{-1}. The interval was prolonged if patients were lightly anaesthetized clinically. Patients started by breathing air and were later changed to breathing oxygen, or started by breathing oxygen and later breathed 33% oxygen in nitrous oxide. We used a Mapleson A system with flows of at least 10 litre min^{-1}. We did not change gas mixture or infusion rate within at least 100 breaths (about 5 min) of the other's being changed, except to add oxygen 1–2 litre min^{-1} if the saturation was less than 90%. This was necessary for a short time after induction when patients were breathing air, but for only two of these patients later during any study. On more than one occasion, changing from a finger to an ear probe improved the apparent saturation.

If a patient sighed, we waited 30 breaths and then gave a matching passive sigh by squeezing the reservoir bag, while the patient was breathing in, to augment that breath to about the same tidal volume as the active sigh; otherwise we aimed for a passive sigh about 2.5 times the average tidal volume. In each patient, we aimed for one pair of sighs (one active and one passive) on the first gas mixture, and one pair on the other. If there was time, we changed gas mixtures again.

Breathing was recorded by respiratory inductance plethysmography (Respitrace model 10.9000), calibrated before induction of anaesthesia by double least squares linear regression against a pneumotachograph (Fleisch head: Godart pneumotachograph 17212), itself calibrated against a 1-litre syringe. The calibration and subsequent analysis were by computer program (BBC B+/Macintosh IIsi running BBC Basic), as reported previously [5]. The inductance plethysmograph was not recalibrated after induction of anaesthesia, but patients were not moved after induction and all comparisons of ventilatory variables were made within patient, or were normalized to a baseline before comparisons were made between patients.

Output from the Respitrace was recorded on magnetic tape (Racal Thermionic Store 4). A continuous capnogram was recorded (Gould Godart Mark III) on paper and on a channel of the tape recorder. Initially, saturation was recorded by hand with other experimental observations; for later patients the signal was recorded onto the second channel of the capnograph pen recorder.

Analysis

The change in tidal volume after a sigh is to about 70% of its preceding mean; the SD of tidal volume is about 10% of mean in the anaesthetized patient, but this variability is approximately doubled after a sigh [2]. From these figures, we estimated that we would need about 60 sighs if we were expecting to distinguish the halving of the effect of a sigh. Inevitably this was arbitrary, as we did not known what to expect, but we decided to wait until we had this number of analysable sighs before any analysis. The first 15 patients yielded 58 sighs, from which the form of the results could be seen. We studied another four patients before deciding to complete the analysis.

For each sigh, we looked at the tidal volume, inspiratory time and expiratory time of the 10 preceding breaths, the sighs and the 20 succeeding breaths. For the active sighs, we also looked at abdominal contribution. We normalized each sigh to the mean of each variable for the five breaths preceding each sigh. The normalized breaths from all analysed sighs were pooled to give normalized means and 95% confidence limits (*t* distribution) on those means. For any given pooled breath, therefore, a mean was significantly different ($P < 0.05$) from baseline if its 95% confidence limits did not include unity. Results are given as fractional values—that is, if a variable is given as 0.72, it is 72% of baseline.

Instead of multiple testing breath-by-breath, we used a summary measure of the effect of each sigh by taking a further mean value of the first group of five (normalized) succeeding breaths. Comparisons on pooled data were made by estimating confidence intervals on differences; comparisons on paired data (active sigh on air with passive sigh on air, or active sigh on air with active sigh on oxygen, from the same patient) were by Wilcoxon matched pairs signed rank test.

Correlation of size of sigh with response to the sigh was checked by a scatter plot and tested formally by Spearman Rank correlation.

StatView (SE+Graphics: Abacus Concepts) was used for standard statistical calculations, and Excel (V3.0: Microsoft) for array calculations, on a Macintosh IIsi computer.

RESULTS

We recorded 46 active sighs and 44 passive sighs. Thirty-three active sighs and 37 passive sighs were analysable. Because we did not manage strict matched pairs (see Patients and Methods) of analysable sighs in all patients, our main analysis was of unpaired comparisons. Figures 2–4 are the pooled observations breath-by-breath; tables I and II are the summary observations, giving details of the sighs and of the group of five succeeding breaths.

Comparison between active and passive sighs

Overall, active and passive sighs were of similar tidal volumes, but the tidal volumes of the active sighs were largest with patients breathing air and smallest with patients breathing nitrous oxide in

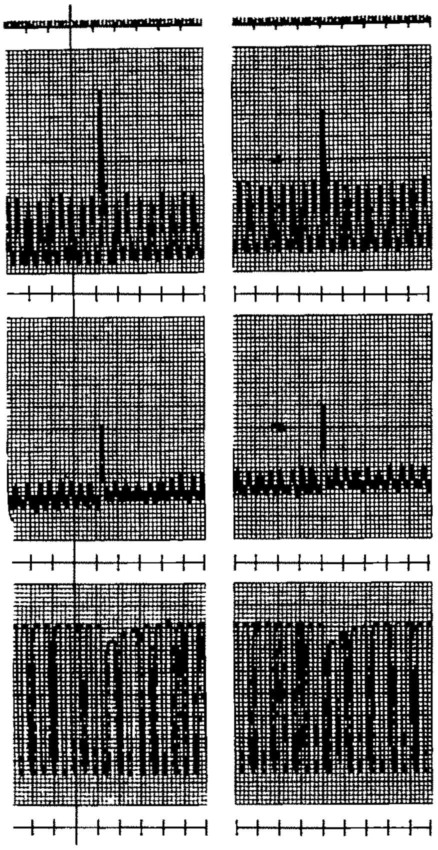

FIG. 1. A spontaneous augmented breath (active sigh), and a manual inflation (passive sigh) in a patient anaesthetized with propofol and breathing air. Top trace: time (seconds). Middle two: rib cage and abdominal output (uncalibrated, with inspiration upwards) from respiratory inductance plethysmography. Lower: capnogram (minimum is zero %, 1 large square = 1%). Thirty breaths (about 1.5 min) separated the sighs. The active sigh was 2.95 × baseline; the mean of the five succeeding tidal volumes 0.84. The passive sigh was 2.67 × baseline; the mean of the five succeeding tidal volumes 0.87.

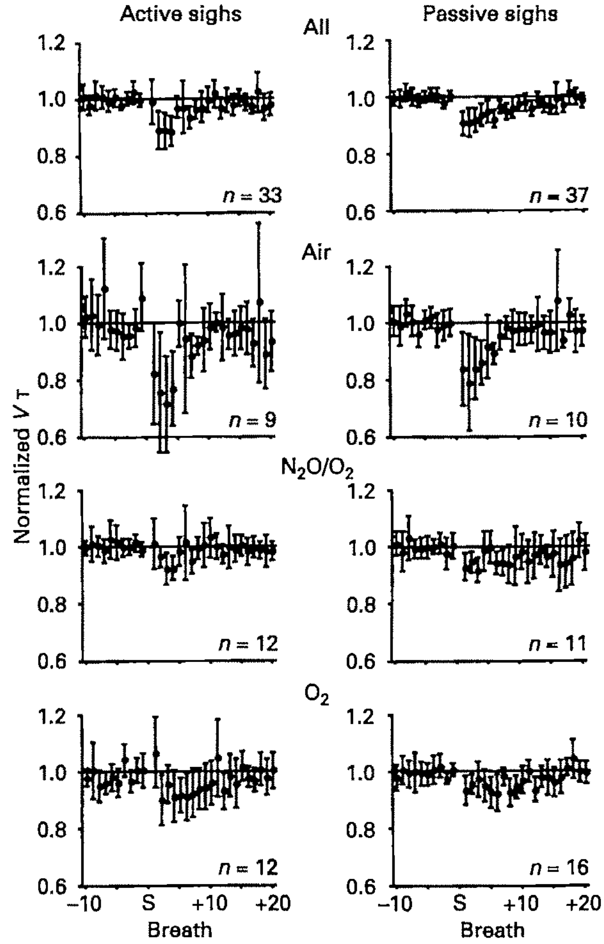

FIG. 2. Effect on tidal volume of active and passive sighs under propofol anaesthesia when breathing air and in hyperoxia. Breaths have each been normalized to the mean tidal volume of the preceding five breaths. Each point and error bar are the means and 95% confidence limits on those means calculated from the summed normalized breaths. The actual sighs are omitted.

oxygen (table I). The tidal volumes of the passive sighs were not different between gas mixtures (table II). We have given only the overall figures for inspiratory and expiratory times of the sighs; both were prolonged more by active than by passive sighs (tables I, II).

Within the limits of measurement, active and passive sighs of similar tidal volume caused similar changes in end-tidal partial pressure of carbon dioxide (fig. 1). The tidal volume of active sighs correlated with the mean tidal volume of the next five breaths (Spearman's $\rho = -0.46$; $P < 0.01$); there was no corresponding correlation for passive sighs (Spearman's $\rho = -0.08$; $P = 0.6$).

The abdominal contribution to the active sighs was 63–127% of baseline, with a mean of 94% (95% CL = 89–99%).

Tidal volume was reduced by about the same amount after active or passive sighs (fig. 2), but inspiratory time was reduced more after an active

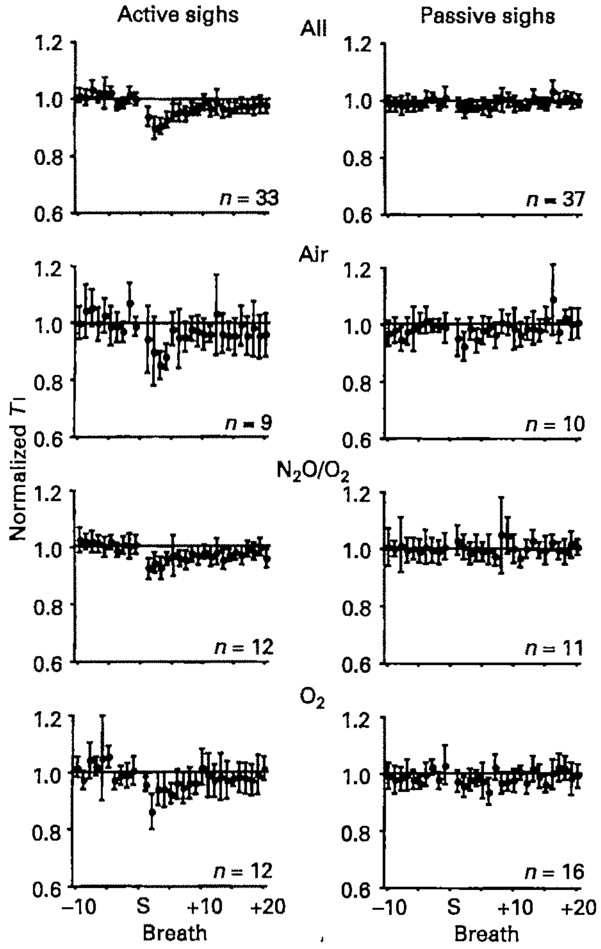

FIG. 3. Effect on inspiratory time of active and passive sighs under propofol anaesthesia when breathing air and in hyperoxia. Breaths have each been normalized to the mean inspiratory time for the preceding five breaths. Each point and error bar are the means and 95 % confidence limits on those means calculated from the summed normalized breaths. The actual sighs are omitted.

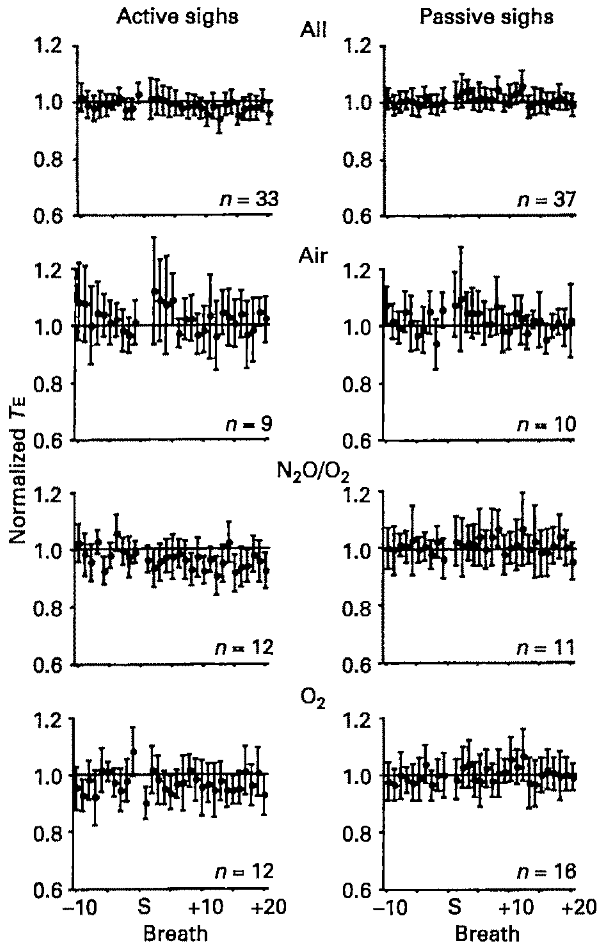

FIG. 4. Effect on expiratory time of active and passive sighs under propofol anaesthesia when breathing air and in hyperoxia. Breaths have each been normalized to the mean expiratory time for the preceding five breaths. Each point and error bar are the means and 95 % confidence limits on those means calculated from the summed normalized breaths. The actual sighs are omitted.

than a passive sigh (fig. 3). Expiratory time is more variable and effects were not so easy to distinguish (fig. 4).

Comparisons between gas mixtures

Sighs, whether active or passive, had more effect on tidal volume when patients were breathing air than when they were breathing 67 % nitrous oxide in oxygen (fig. 2). For active sighs, the difference was 0.17 (95 % CL 0.07–0.27; $P < 0.001$); for passive sighs, the difference was 0.11 (95 % CL 0.03–0.19; $P < 0.01$). There was a similar difference between sighs breathing air and breathing 100 % oxygen. For active sighs, the difference was 0.14 (95 % CL 0.03–0.25; $P < 0.01$); for passive sighs, the difference was 0.10 (95 % CL 0.03–0.17; $P < 0.01$). Sighs with all three gas mixtures affected inspiratory time more if the sigh was active (fig. 3). Only sighs with air prolonged expiratory time, with the same proviso as above concerning variability (fig. 4).

TABLE III. *Paired comparisons of spontaneous augmented breaths (active sighs: AS) and manual lung inflations (passive sighs: PS) in patients anaesthetized with propofol and breathing air or a hyperoxic mixture (ox). Values are normalized to the mean of the five breaths preceding the sigh. The number of comparisons is shown (n), and for each paired comparison: the means, the difference between the means, and the probability by Wilcoxon matched pairs signed rank test.* V_T = *tidal volume;* T_I = *inspiratory time;* T_E = *expiratory time*

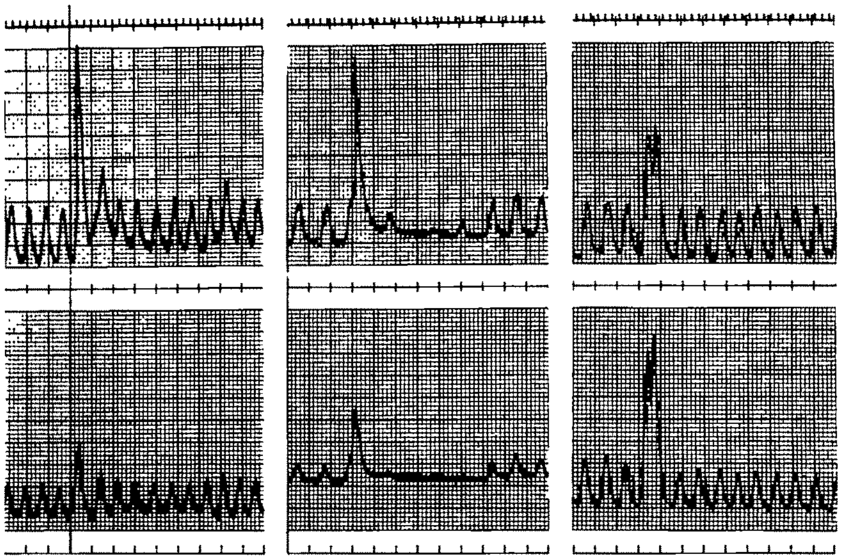

FIG. 5. Three sighs not included in the analysis; patients anaesthetized with propofol and breathing air. Top traces: time (s); middle and lower traces: rib cage and abdominal output (uncalibrated, with inspiration upwards) from respiratory inductance plethysmography. Left: a manual inflation (passive sigh) has caused arousal; the succeeding breath has an increased tidal volume. Middle: A spontaneous augmented breath (active sigh) has caused a short period of virtual apnoea. Right: A passive sigh has triggered an active sigh.

Mean inspiratory flow (calculated as mean tidal volume divided by mean inspiratory time) was reduced after sighs with air but was *greater* for the five succeeding breaths of an active sigh with a hyperoxic mixture.

Paired comparisons

We were able to compare four groups of paired sighs: active sighs on air and passive sighs on air ($n = 7$, from five patients); active sighs with hyperoxic mixtures and passive sighs with hyperoxic mixtures ($n = 17$, from 13 patients); active sighs with air and active sighs with hyperoxic mixtures ($n = 5$, from four patients); and passive sighs with air and passive sighs with hyperoxic mixtures ($n = 6$, from five patients) (table III). Although small numbers make comparisons imprecise, the trend of the paired comparisons for tidal volume and inspiratory time supports the pooled data, in that tidal volume was affected by gas mixture more than by type of sigh and inspiratory time was affected more by type of sigh than by gas mixture. The change in expiratory time was inconsistent: active sighs with air prolonged expiratory time more than passive sighs with air, and active sighs with oxygen *decreased* expiratory time.

Sighs not included for analysis

Twenty sighs were not analysed (13 of them active sighs). Eight were part of—or triggered—an obvious arousal reaction (fig. 5, left), in which there was limb movement or transient tachycardia. Two sighs caused a short apnoea (fig. 5, middle). One passive sigh triggered an active sigh (fig. 5, right), and was excluded. Two active sighs occurred too soon after a change of gas mixture. Two could not be analysed because of sudden shifts in the Respitrace signal shortly after the sighs. The other five excluded sighs occurred when breathing was unstable or irregular, and the sigh was imposed on a pattern of changing tidal volume.

DISCUSSION

The alteration in breathing pattern caused by sighs was, in general, much as described previously [2]. The similarity of reduction in tidal volume after active and passive sighs, and the way this reduction was less in hyperoxia, supports the hypothesis that the reduction is mediated by the chemoreceptors.

As in the previous study [2], most (16 of 19) of our patients were women. We did not record stage of menstrual cycle, or if they were receiving oral contraceptives, so can make no comment on whether differences between patients were influenced in any way by progestagens.

Active sighs shortened inspiratory time more than passive sighs did, and gas mixture had less effect on inspiratory time than on tidal volume. We cannot say that the change in chemoreceptor input had no effect on inspiratory time (there may be some difference between the effect of passive sighs in air and in hyperoxia), but we suggest that much of the effect on inspiratory time is either an in-built response of the respiratory centre when the sigh is generated, or caused by a mechanoreceptor afferent response not mimicked by a passive sigh.

We could not distinguish an effect of nitrous oxide on the pattern after the sigh. Active sighs with nitrous oxide had smaller tidal volumes than sighs with either air or oxygen. We cannot say if this was because of the nitrous oxide. Overall, hyperoxic active sighs had smaller tidal volumes than active sighs with air, which could have affected the tidal volume response to the sigh. As tidal volume was also affected more after a passive sigh with air, when the tidal volumes of the actual sighs were not affected by gas mixture, we believe that hyperoxia does modify the tidal volume response.

What is clear from this study, and which we did not notice during the previous work, is that a sigh can cause, or is part of, arousal. One difference from the previous study [2] was the use of the laryngeal mask airway. Afferents from the larynx form part of many reflexes in the control of breathing. It is unlikely that the laryngeal mask alters the general pattern of the response to sighs—our observations of the effect of active sighs was much the same in this study as in the previous one—but perhaps a sigh is more likely to cause arousal if there is a laryngeal mask in place. Arousal, easy to identify when accompanied by an increase in heart rate occurring with the sigh and continuing for a few beats, complicates analysis of the effects of sighs. The chemical change reduces the tidal volume, but arousal increases it, and there is no easy way of distinguishing between these opposing effects. If there was obvious arousal, we did not include that sigh in the analysis. Arousal was more common with active sighs than with passive sighs. When the arousal had subsided, breaths then followed the usual post-sigh pattern, but the smallest tidal volume after a sigh was the third or fourth breath or later. We suggest that the increase in mean inspiratory flow after hyperoxic *active* sighs was caused by this arousal, and that the decrease in flow after hyperoxic *passive* sighs is a truer reflection of the effect of the change in chemical stimulus: less than occurs with air. In work on cats [6], the rate of increase in phrenic activity after spontaneous and provoked sighs was usually greater and the inspiratory time shorter after the sigh; this study did not include the effect of simple passive inflations.

There was correlation between the tidal volume of active sighs, but not of passive sighs, with the subsequent effect on tidal volume, which we suggest is because of the wider range of tidal volumes of active sighs. There are many sources of variability between tidal volume of sigh and effect: the calibration of inductance plethysmography varies with tidal volume; the end-tidal measurement of carbon dioxide is not the arterial partial pressure; and chemoreceptor reflex sensitivity varies between individuals.

As previously [2], the effect of sighs on expiratory time was unclear, partly because of its greater variability. The only unreported observation on expiratory time in anaesthetized patients about which we are certain is that the expiratory time *of* a passive sigh—of the breath on which it is imposed—is usually prolonged: the next breath is delayed. Bowes, Andrey and Kozar [7] reported in dogs that this prolongation did not occur if the carotid bodies were denervated. We saw no differences in the expiratory times of passive sighs between gas mixtures.

That a sigh can cause arousal, which then affects the ventilatory drive of a breath or two after the sigh, is another reason why the suggestion of Khoo and Marmarelis [3], of using the effect of a sigh to estimate the gain of the peripheral chemoreflex, might not be easy to apply to anaesthetized man.

I.V. ANAESTHESIA WITH PROPOFOL USING A TARGET-CONTROLLED INFUSION SYSTEM: COMPARISON WITH INHALATION ANAESTHESIA FOR GENERAL SURGICAL PROCEDURES IN CHILDREN

E. DOYLE, W. McFADZEAN AND N. S. MORTON

SUMMARY

We studied 40 children undergoing general surgical procedures. They were allocated randomly to receive induction of anaesthesia with propofol 3–5 mg kg^{-1} followed by maintenance with halothane and an appropriate regional block, or induction and maintenance of anaesthesia with a computerized, target-controlled infusion of propofol with a regional block. All patients breathed a mixture of 67% nitrous oxide in oxygen via a laryngeal mask airway. Both techniques provided adequate anaesthesia and operating conditions. There were no significant differences between the groups in heart rate, mean arterial pressure and end-expired carbon dioxide concentration during anaesthesia. There was no significant difference in the recovery times of the two groups. (Br. J. Anaesth. 1993; **70**: 542–545)

KEY WORDS

Anaesthesia: paediatric. Anaesthetic techniques: intravenous infusion. Anaesthetics, intravenous: propofol.

Propofol is associated with prompt, rapid recovery from anaesthesia when used as an induction agent in adults [1]. Compared with induction of anaesthesia with thiopentone, propofol produces earlier return of clinical indices of recovery, protective reflexes and psychomotor function [2, 3], but these differences are not observed if anaesthesia is maintained for more than 30 min using halothane [4].

In paediatric practice, it has been shown that children undergoing day-case surgical procedures under general anaesthesia with isoflurane, with or without regional block, recover more quickly if their anaesthesia is induced with propofol than with thiopentone [5, 6]. Other paediatric studies have compared propofol for both induction and maintenance of anaesthesia with thiopentone induction and maintenance with a volatile agent [7, 8]. These studies in dental and E.N.T. surgery found that propofol compared well with inhalation maintenance and produced significantly quicker recovery from anaesthesia. In a day-case study [8] there was a shorter time to discharge in the propofol group.

A standard technique for many brief general surgical procedures in children is to combine a general anaesthetic with an appropriate regional block to provide perioperative analgesia. This study was designed to compare a technique of induction and maintenance of anaesthesia using a propofol infusion combined with regional block, and a technique of induction with propofol followed by maintenance using halothane combined with a regional block.

PATIENTS AND METHODS

The study was approved by the local Ethics Committee and informed written parental consent was obtained. We studied 40 children of ASA grades I and II undergoing general surgical procedures expected to last less than 1 h. Exclusion criteria included age less than 1 yr, weight less than 10 kg, allergy to eggs and a surgical procedure for which an appropriate regional block could not be performed.

TABLE I. *Patient data and details of operations in groups H (halothane maintenance) and P (propofol maintenance) (number or mean (range))*

	Group H	Group P
Sex (M/F)	19/1	17/3
Age (months)	67.6 (16–154)	66.0 (13–141)
Weight (kg)	20.7 (12.5–32.0)	20.3 (10.2–40.3)
Duration of anaesth. (min)	30.6 (9–52)	33.3 (11–60)
Time end of agent to end surgery (min)	6.2 (2–10)	5.3 (3–8)

Correspondence to E.D.

Premedication comprised EMLA cream (lignocaine 25 mg g^{-1} and prilocaine 25 mg g^{-1}) applied to the backs of both hands at least 1 h before induction. In the anaesthetic room, pre-induction measurements of heart rate, arterial pressure and arterial oxygen saturation were obtained using a Dinamap non-invasive arterial pressure monitor with an appropriate size of cuff and a Nellcor pulse oximeter. A suitable vein was cannulated with a 22- or 24-gauge cannula.

Patients were allocated randomly (by computer-generated list) to two groups of 20 patients each. Group H (halothane maintenance) received an induction dose of propofol 3–5 mg kg^{-1} (with lignocaine 0.2 mg kg^{-1}) followed by maintenance of anaesthesia with 67 % nitrous oxide and 0.5–2.0 % halothane in oxygen as necessary to maintain an adequate depth of anaesthesia. In group P (propofol maintenance), anaesthesia was induced and maintained with an infusion of propofol delivered by an Ohmeda 9000 infusion pump driven by a Psion II computer containing a program designed to achieve and maintain preselected blood concentrations of propofol [9, 10]. The initial blood targets chosen were in the range 8–14 μg ml^{-1} and these were reduced subsequently to maintain an adequate depth of anaesthesia. These patients breathed a mixture of 67 % nitrous oxide in oxygen. Episodes of apnoea, cough, hiccup and involuntary movements which occurred during induction were noted.

In all patients, a laryngeal mask airway of appropriate size was used to maintain the airway during anaesthesia. An appropriate regional block was performed after induction of anaesthesia and before the start of surgery.

In both groups, measurements of heart rate, arterial pressure and arterial oxygen saturation were taken at 1, 2, 3, 4, 5, 10 and 15 min after induction and at further 5-min intervals until the end of surgery. End-expired carbon dioxide concentration was measured using a Datex Capnomac Ultima when the patient had been moved into theatre and was recorded at 5-min intervals until the end of surgery. Anaesthetic agents were discontinued at the start of skin closure. At the end of surgery, patients were transferred to the recovery area breathing 100 % oxygen via the laryngeal mask airway, which was removed after return of the gag reflex. The time of spontaneous eye opening was noted in the recovery area.

Before the patient was discharged to the surgical ward, the level of comfort and analgesia were assessed clinically.

Data were analysed statistically using Student's *t* test for normally distributed data and the Wilcoxon two-sample rank sum distribution for non-parametric data.

RESULTS

The two groups were similar in age, weight and operative details (table I). The mean dose of propofol required to induce anaesthesia in group H was 3.9 mg kg^{-1} (range 3.0–5.1 mg kg^{-1}). In group P the mean induction bolus of propofol was 3.9 mg kg^{-1} (range 2.8–5.1 mg kg^{-1}) and infusion rates of propofol for maintenance of anaesthesia ranged from 18.3 mg kg^{-1} h^{-1} to 36.2 mg kg^{-1} h^{-1} (mean 25.6 (SD 4.8) mg kg^{-1} h^{-1}).

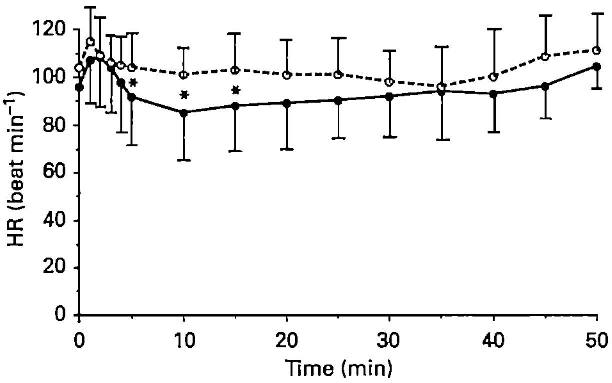

FIG. 1. Mean (SD) heart rates (HR) of patients in groups H (●) and P (○) at intervals after induction of anaesthesia. Time 0 = pre-induction reading. *$P < 0.05$ for difference between means.

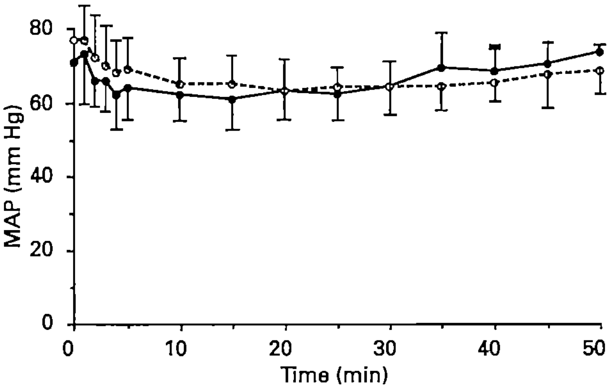

FIG. 2. Mean (SD) mean arterial pressures (MAP) of patients in groups H (●) and P (○) at intervals after induction of anaesthesia. Time 0 = pre-induction reading.

Two patients (10 %) in group H and four (20 %) in group P experienced pain or discomfort during induction of anaesthesia with propofol. Six (30 %) of patients in group H and five (25 %) in group P were apnoeic for 15–60 s after induction of anaesthesia. Involuntary movements occurred for a few seconds after induction of anaesthesia in five (25 %) patients in group H and three (15 %) patients in group P.

All patients were judged to be anaesthetized adequately and operating conditions were good in all cases. The mean heart rates in group P tended to be slightly faster than those in group H and the difference was just significant at the 5 % level on three occasions (5, 10 and 15 min) (fig. 1).

There was no significant difference in arterial pressure between the two groups at any time (fig. 2), and no significant difference in mean end-expired carbon dioxide concentration between them except at 15 min (fig. 3).

There was no significant difference between the groups in the time taken to spontaneous eye opening after discontinuation of the maintenance anaesthetic (10.5 min (range 3–32 min) in group H; 13.5 min (range 4–36 min) in group P). The calculated blood concentration of propofol at which patients in group P awoke was in the range 0.3–2.6 μg ml^{-1} (mean 1.4 μg ml^{-1}).

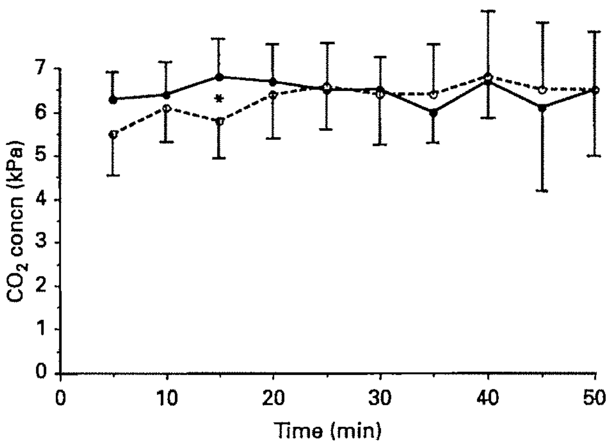

FIG. 3. Mean (SD) end-tidal carbon dioxide concentration of patients in groups H (●) and P (○) at intervals after induction of anaesthesia. *$P < 0.05$ for difference between means.

One patient in group H and two patients in group P complained of pain at the operative site and were treated with diclofenac sodium 1 mg kg^{-1} as required. All other patients were comfortable on recovery from anaesthesia.

DISCUSSION

More rapid recovery occurs after induction of anaesthesia with propofol compared with thiopentone in both children [5, 6] and adults. In these previous studies, anaesthesia was maintained with a volatile anaesthetic agent. The use of propofol as the induction agent for paediatric general surgery day-cases has been shown to produce earlier recovery from anaesthesia in all patients and earlier discharge in children aged more than 5 yr, although not in those younger than 5 yr [5].

Our study was designed to see if maintaining anaesthesia with an infusion of propofol rather than a volatile agent would produce larger differences in recovery times than the relatively small differences seen between children in whom anaesthesia was induced with propofol and those given thiopentone. The numbers of patients in the two groups were calculated to give the study a 95% chance of detecting a difference in recovery times that would be significant at the 5% level if differences in recovery times of the same magnitude as in other paediatric studies occurred [6–8].

There was a preponderance of boys in our study because paediatric day-case surgery tends to include a number of exclusively male conditions such as circumcision and orchidopexy. The differing numbers of particular regional blocks in groups H and P were a reflection of the normal practice of different consultant anaesthetists in performing regional blocks for circumcision, orchidopexy and inguinal hernia repair. Caudal anaesthesia and ilioinguinal nerve block have been shown to be equally effective and longlasting when used for orchidopexy and inguinal hernia surgery [11]. Caudal block and dorsal nerve block of the penis have been shown to have similar effectiveness and duration of analgesia when used for circumcision [12, 13]. We wished to reflect normal practice in day-case surgery during the study and, for this reason and given that the caudal, ilioinguinal nerve and dorsal nerve of penis blocks are equivalent when used appropriately, we did not standardize the regional blocks, which were performed by a registrar or senior registrar under the supervision of a consultant. Again, this was to reflect normal clinical practice in a teaching hospital. The fact that almost all patients (19 of 20 in group H and 18 of 20 in group P) were comfortable in the recovery room suggests that the blocks were generally effective and appropriate.

We found that the two groups were similar in all respects. Induction of anaesthesia was satisfactory in both groups, with a low incidence of minor side effects. Maintenance of anaesthesia was straightforward in both groups and operating conditions satisfactory.

Spontaneous eye opening has been shown [8] to be a sensitive indicator of recovery from general anaesthesia in children; there was no significant difference between the groups in the time from discontinuation of anaesthesia to spontaneous eye opening. This finding contrasts with a study of maintenance of anaesthesia by halothane or propofol in paediatric dental outpatients [8] in which significantly earlier recovery occurred in the propofol group. In that study, the mean duration of anaesthesia was 8.1 min in the thiopentone group and 6.3 min in the propofol group, compared with 30.6 min in group H and 33.3 min in group P in our study. The cumulative effects of anaesthetic agents during longer procedures may abolish the differences observed after short procedures [4]. The use of a regional block in our patients may also have reduced any tendency to quick recovery by reducing or eliminating postoperative pain.

Borgeat and colleagues [7] compared a thiopentone–halothane technique with a propofol induction and maintenance technique for E.N.T. procedures. Their patients were paralysed and no regional block was performed. The mean durations of surgery were 35 min (thiopentone–halothane) and 37 min (propofol) and there were significantly quicker times to tracheal extubation in the propofol group.

The lack of any significant cardiovascular or respiratory differences between the groups in our study is in agreement with that of Borgeat and colleagues [7]. This indicates that maintenance of anaesthesia by means of a target-controlled infusion of propofol in children breathing spontaneously without an opioid is not unduly depressant to the cardiovascular or respiratory systems.

PHARMACOKINETICS OF PROPOFOL ADMINISTERED BY INFUSION IN DOGS UNDERGOING SURGERY

A. NOLAN AND J. REID

SUMMARY

*We have investigated the pharmacokinetics of propofol in seven beagle dogs undergoing surgery for implantation of s.c. tissue pouches. Blood concentrations of propofol were measured using high pressure liquid chromatography with fluorescence detection. After premedication with acepromazine and papaveretum and induction of anaesthesia with propofol 4 mg kg^{-1} i.v., anaesthesia was maintained with propofol 0.4 mg kg^{-1} min^{-1} and 67% nitrous oxide in six dogs. In the seventh dog, the infusion rate was increased to 0.6 mg kg^{-1} min^{-1} in order to achieve surgical anaesthesia. The mean elimination half-life was 322.3 (sem 27.0) min, mean volume of distribution at steady state 6.510 (0.524) litre kg^{-1}, mean body clearance 50.1 (3.9) ml kg^{-1} min^{-1} and mean residence time 131.6 (8.9) min. The blood propofol concentrations achieved using this standard dosing regimen showed wide variation among individuals. All dogs recovered rapidly from anaesthesia. The mean time to extubation was 7.6 min and to standing unaided was 30.7 min from the end of the infusion. (*Br. J. Anaesth. 1993; **70**: 546–551)

KEY WORDS
Anaesthetics, intravenous: propofol.

We have previously reported the pharmacokinetics of propofol in the dog, which remains a popular model in medical research, despite a tendency to favour small laboratory animals for experimental purposes. When propofol is administered as either a single bolus or as a bolus before maintenance of anaesthesia with halothane, body clearance was greater in dogs than in man, elimination half-life was shorter and recovery from anaesthesia equally rapid [1]. However, the sampling period in that study was relatively short (6 h). Campbell and colleagues [2] have suggested that, when blood samples are collected over a relatively short period of time, this apparently rapid elimination may be misleading. These and other workers have reported longer elimination half-lives and lower clearance values which suggested that elimination of propofol from the body was relatively slower than reported previously [2–5]. This could be significant when propofol is used by infusion for the maintenance of anaesthesia in long surgical procedures. Albanese and colleagues [6] reported a mean elimination half-life of 1878 min and an increased clearance value in patients undergoing long-term infusions, but in this study there was considerable interpatient variation.

Consequently, we decided to investigate the pharmacokinetics of propofol infusion in dogs undergoing identical body surface surgery, in order to identify the blood concentrations required to maintain surgical anaesthesia and to define pharmacokinetic parameters using a longer sampling regimen. The work was carried out under Home Office Licence PPL 60/01048.

METHODS

Phamacokinetic studies in dogs given a single bolus dose of propofol have been carried out [1] and the mean results for volume of the central compartment (Vc) and body clearance (Cl) were used to estimate a loading dose (Xd) and infusion rate for this study as follows: $X\text{d} = C^{ss}.Vc$, where C^{ss} is the target concentration at steady state and infusion rate $= Cl.C^{ss}$. On the basis of a pilot infusion study carried out in bitches undergoing ovarohysterectomy, the target range for C^{ss} was set at 5–7 µg ml^{-1}.

We studied seven beagle dogs (three male) aged 8–9 months, weights 16–26.5 kg and free from clinical signs of disease. They were to be anaesthetized for implantation of four s.c. tissue cages in the flank region. Before anaesthesia, routine biochemical and haematological screening was carried out on each dog.

Food was withheld for all animals for 12–16 h, but water was freely available until 3 h before induction of anaesthesia. All dogs were premedicated with acepromazine maleate (ACP; CVet) 0.05 mg kg^{-1} and papaveretum (Omnopon; Roche) 0.4 mg kg^{-1}, given together i.m. 30 min before induction of anaesthesia. Propofol (Rapinovet; Pitman Moore) 4 mg kg^{-1} was injected as a bolus via a preplaced cannula located in the right cephalic vein. After tracheal intubation, the dogs were allowed to breathe spontaneously a mixture of 67% nitrous oxide in

oxygen via a Magill non-rebreathing system with a fresh gas flow rate of 200 ml kg^{-1} min^{-1}.

One minute after induction, a zero order i.v. infusion of propofol 0.4 mg kg^{-1} min was begun using a volumetric infusion pump (Flo-Gard 6200; Baxter) and continued for 60 min. If anaesthesia was inadequate, the infusion rate was increased until the desired plane of anaesthesia was achieved. In all animals, the non-steroidal antiinflammatory drug flunixin meglumine (Finadyne; Schering Plough Animal Health) 1 mg kg^{-1} was injected s.c. 2 h after the infusion was terminated.

Venous blood samples (1.5 ml) were collected from a cannula located in the left cephalic vein, immediately before and during the infusion, and after it was terminated. Times of collection during the infusion were 2, 5, 10, 15, 20, 40 and 60 min. After the infusion was stopped, samples were taken at 2, 5, 10, 20, 30, 45, 60 min and then at 2, 3, 4, 6, 9, 20 and 24 h. Samples, collected in tubes containing potassium oxalate, were cooled immediately and stored at 4 °C until analysis. All samples were assayed within 2 weeks of collection and previous investigations have shown that blood stored in this way retains in excess of 98 % of its original propofol concentration. Whole blood concentrations of propofol were measured by high pressure liquid chromatography with fluorescence detection [7]. The limit of detection was approximately 5 ng ml^{-1} and the intra-assay coefficient of variation was 2.9 %.

Routine monitoring was carried out during anaesthesia. Heart rate and ventilatory frequency, systemic arterial pressure, end-tidal partial pressure of carbon dioxide ($P\text{E}'_{CO_2}$) and oxygen saturation were measured at 5-min intervals. Arterial pressure was monitored using a Dinamap pressure monitor (Critikon Canada Inc.) with an appropriately sized cuff placed over the middle coccygeal artery. $P\text{E}'_{CO_2}$ was monitored on a breath-by-breath basis using a carbon dioxide analyser (Normocap; Datex). Oxygen saturation was measured using a pulse oximeter (Ohmeda) located on the tongue.

Recovery times (tracheal extubation, head lift, sternal recumbency and standing unaided) were measured from the time the infusion was switched off. The blood concentration of propofol at the time of tracheal extubation and head-lift was calculated retrospectively by extrapolation from each individual propofol concentration–time curve.

The apparent elimination half-life, $T_{\frac{1}{2}}^{\beta}$ was calculated from the terminal log-linear portion of the post-infusion decay curve of blood concentration of propofol *vs* time, using the curve stripping programme CSTRIP [8]. The non-compartmental pharmacokinetic parameters, volume of distribution at steady state (V^{ss}), clearance (Cl) and mean residence time (MRT) were calculated according to standard methods using the statistical moment theory [9]. Area under the blood concentration (tC_P)–time (t) plots to infinity (AUC), and the area under the first moment curve (AUMC = $tC_P \times t^2$) were calculated from the first to the last blood propofol sample using the trapezoidal rule. An estimate of the infinite part of the curve was obtained from $t'C_P/\beta$, where t' = last measured blood concentration of propofol and β = overall elimination rate constant. An estimate of the infinite part of the AUMC plot was obtained from $t'C_P \times t'/\beta$. MRT corrected for infusion duration, was calculated from AUC and AUMC (MRT = AUMC/AUC − T/2) where T is the infusion time. V^{ss} was calculated from $Cl \times$ MRT [10].

RESULTS

Six of the seven dogs had a constant rate infusion, while the seventh required two increases in infusion rate. Consequently, results for blood propofol concentrations are expressed as a mean for six animals (dogs Nos 1–6). Blood concentrations of propofol varied between 3.77 and 5.52 µg ml^{-1} as the infusion was started. A mean concentration of 5 µg ml^{-1} (range 3.34–6.60 µg ml^{-1}) was achieved within 10 min, indicating a rapid approach towards the target concentration range, although the between-animal variation was large. The propofol concentration increased gradually over the next 50 min until the infusion was switched off, at which point the mean concentration was 5.84 (SEM 0.54) µg ml^{-1} (range 4.0–7.1 µg ml^{-1}) (fig. 1A). In dogs Nos 1–6, surgery began within 15 min of the start of the infusion, at which time the blood concentrations of propofol were in the range 3.5–5.8 µg ml^{-1}. After cessation of the infusion, the blood concentration of propofol declined in a polyexponential manner (fig. 1B). Measurable blood concentrations of propofol were present in all dogs for 25 h.

Tracheal intubation was not possible immediately after induction in dog No. 7, and after 10 min the infusion rate was increased to 0.5 mg kg^{-1} min^{-1}. Four minutes later, the infusion rate was increased again to 0.6 mg kg^{-1} min^{-1} in order to achieve surgical anaesthesia. At 15 min, this animal had a blood concentration of propofol 5.4 µg ml^{-1} and intubation was successful. When surgery began 20 min after the start of the infusion, the blood concentration of propofol was 5.82 µg ml^{-1}. The rate of infusion was reduced to 0.5 mg kg^{-1} min^{-1} after 40 min and again 6 min later to 0.4 mg kg^{-1} min^{-1}. At the end of the infusion period the blood concentration of propofol was 7.9 µg ml^{-1}. During surgery, although no movement was recorded and cardiovascular variables remained stable, an increase in ventilatory frequency was evident as s.c. tunnelling was performed.

Clinically, all animals were in a light plane of anaesthesia. A brisk palpebral reflex was present for the first 30–40 min of the infusion in five dogs and on occasions spontaneous blinking was noted.

The mean elimination half-life for all seven dogs was 322.3 (27.0) min, mean clearance 50.1 (3.9) ml kg^{-1} min^{-1}, V^{ss} 6.510 (0.524) litre kg^{-1} and MRT 131.6 (8.9) min. The pharmacokinetic variables for each dog are shown in table I.

Mean values for physiological parameters are shown for six dogs, omitting dog No. 7 which received a greater total dose of propofol than the other six animals. Systolic arterial pressure decreased from 130 (5) mm Hg 5 min before induction to a smallest value of 111 (3) mm Hg 5 min after

induction (fig. 2). Thereafter, it remained relatively stable, varying between 112 and 121 mm Hg. The diastolic pressure followed a similar pattern (fig. 2) with a maximum decrease of 20% recorded 5 min after induction. During anaesthesia, the heart rate varied minimally from a preinduction value of 85 beat min^{-1} (fig. 2). Post-induction apnoea was recorded in one dog, spontaneous ventilation returning after 3 min. $P\text{E}'_{CO_2}$ values increased from a mean value of 5.9 (0.4) kPa 5 min after induction to 6.7 (0.3) kPa, while ventilatory frequency remained largely unchanged from preinduction values (fig. 3).

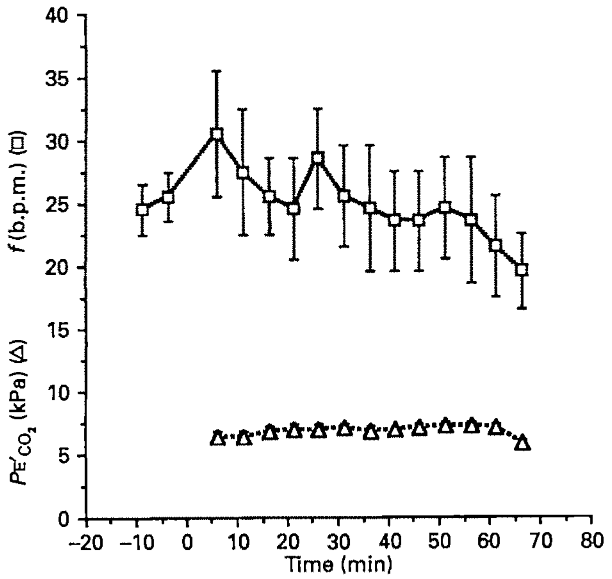

FIG. 3. Changes in ventilatory frequency (*f*) (□) and end-tidal partial pressure of carbon dioxide ($P_{E'CO_2}$) (△) tension during a 60-min propofol infusion (mean, SEM of six dogs).

TABLE II. *Recovery times measured from the end of a 1-h infusion of propofol 0.4 mg kg^{-1} min^{-1}*

Dog No.	Extubation (min)	Head-lift (min)	Sternal recumbency (min)	Standing unaided (min)
1	8	14	55	69
2	4	4	14	18
3	6	8	13	32
4	6	13	19	40
5	10	12	18	23
6	11	13	17	18
7	8	9	10	25
Mean	7.6	10.4	20.8	30.7
SEM	1.0	1.5	6.3	8.0

Oxygen saturation was not measured before induction of anaesthesia, but remained greater than 90 % throughout the course of anaesthesia.

Recovery from anaesthesia was rapid in all dogs (table II). One dog remained in lateral recumbency for 55 min, but appeared fully conscious. The mean blood concentration of propofol at extubation was 2.3 μg ml^{-1} (range 2.1–2.9 μg ml^{-1}) and at head lift 2.1 μg ml^{-1} (range 1.7–2.7 μg ml^{-1}).

DISCUSSION

The combination of a bolus dose followed by a relatively rapid infusion of propofol allowed us to achieve surgical anaesthesia within 20 min in all dogs. Respiratory depression was evident throughout anaesthesia, but was considered acceptable in this group of spontaneously breathing dogs. $P_{E'CO_2}$ had returned to a mean of 5.3 kPa within 5 min of the end of the infusion, indicating that there was little respiratory depression persisting into the recovery period.

Arterial hypotension occurs commonly during induction of anaesthesia with a bolus injection of propofol, and this has been attributed to a decrease in systemic vascular resistance [11–13]. However, more recently Puttick and colleagues [14] have demonstrated that reduction in preload and myocardial contracility contributed to propofol-induced hypotension in a group of open chested dogs. In the present study, the greatest changes in systolic and diastolic arterial pressures were recorded 5 min after induction of anaesthesia. However, these dogs had received acepromazine, a phenothiazine tranquillizer, as part of the premedicant 30 min before the induction of anaesthesia. In addition to its tranquillizing properties, this drug causes moderate hypotension in the dog as a result of peripheral vasodilatation [15], which would contribute to the hypotension recorded during induction and maintenance of anaesthesia.

Previous studies of propofol in humans and experimental animals have shown that individual variations in blood concentrations of propofol may occur [14, 16]. Similarly, in the present study, marked variation in blood concentrations of propofol occurred, despite the identical infusion rate. Such variation was not reflected clinically, however, as six dogs appeared to be in a similar anaesthetic plane. The exception was dog No. 7: the trachea could not be intubated until the blood concentration of propofol reached 5.4 μg ml^{-1}.

In man, there seems to be wide variation in blood concentrations of propofol associated with the abolition of response to surgical stimulus, with the concurrent use of other drugs making comparisons difficult [17–19]. Turtle and others reported that a propofol concentration of 5.9 μg ml^{-1} abolished movement to skin incision in 95 % of patients who had received lorazepam as a premedicant [20]. This value is similar to that found in our dogs, which had been sedated with a neuroleptanalgesic mixture. However, the additional analgesic activity of this mixture must be set against the substantially lower efficacy of nitrous oxide in dogs [21] compared with man.

Gepts and co-workers [22] administered propofol to patients by continuous infusion at a maximum rate of 0.15 mg kg^{-1} min^{-1} and found that there was an initial increase in blood concentration over 10 min, followed by a slower rate of increase over the infusion period. After the infusion they measured a long third phase (355 min), which they suggested was unlikely to play a significant role in the rate of recovery of consciousness because blood concentrations were so small. In our canine study, blood concentrations of propofol followed a similar pattern, but we consider that a zero order infusion of this magnitude (0.4 mg kg^{-1} min^{-1}), if maintained for long periods, could result in delayed recovery from anaesthesia because of cumulation of propofol in tissue stores. Limited clinical experience of prolonged infusion of propofol to dogs supports this view [23].

During the post-infusion decay of propofol from blood, three of seven animals showed small secondary peaks, dogs Nos 1 and 2 at 240 min and dog No. 4 at 45 min, all of which were less than 20 % of the previous sample value. This is in contrast with infusion studies in man which have demonstrated occasional profound increases in blood concentration of propofol during the recovery period [5, 6, 18].

Previous studies in the dog have reported a $T_{\frac{1}{2}}^{\beta}$ of 90.9 min with a high clearance value of 58.6 ml kg^{-1} min^{-1} [1]. This clearance is in excess of liver blood flow [24] and lends weight to the argument for an extrahepatic site of metabolism. Morgan, Campbell and Crankshaw [3] suggested that, in humans, clearance values from single bolus studies were an overestimate of the true body clearance when applied to infusion studies, but we have shown that in the dog the mean clearance for propofol by infusion, 50.1 ml kg^{-1} min^{-1}, is similar to that found in single bolus studies. However, the elimination half-life was considerably greater than that calculated from single dose studies. This is probably a reflection of the fact that samples were collected over a much longer period of time. Similar findings have been demonstrated in patients undergoing long-term mechanical ventilation who received propofol by infusion [6] and other workers investigating the pharmacokinetics of propofol from infusion studies have reported a variety of prolonged half-lives of 13.1–44.7 h [3].

The volume of distribution was large, 6.5 litre kg^{-1}, confirming the extensive distribution of propofol from blood into tissues, and is not unexpected for such a highly lipophilic drug. These values are greater than those recorded in humans by some groups [18, 22, 25], but less than that reported by Albanese and coworkers [6].

Blood concentration of propofol at awakening has been measured in man and the evidence suggests that, when propofol is given by infusion, the range is 0.74–1.66 μg ml^{-1} [22]. In a study carried out in pregnant women, it was reported that patients who received a greater infusion rate during surgery opened their eyes at the same time (mean 6 min) as those that received a lesser infusion rate, although the blood concentrations of propofol were significantly greater (1.74 μg ml^{-1} *vs* 1.24 μg ml^{-1}) [26]. It is difficult to assess time of awakening in dogs. We regard the ability to maintain head-lift as the criterion for awakening in animals, although it may not be totally comparable to eye opening in man. The blood concentrations of propofol at awakening obtained in these dogs, greater than recorded in humans and from dogs given a single bolus dose of propofol [1], probably reflect the greater infusion rate used in this study, but the recovery times compare favourably.

In conclusion, we have shown that although the elimination half-life of propofol in dogs was considerably longer than that recorded from single bolus dose studies, body clearance was high. In addition, there was considerable between-animal variation in blood concentrations of propofol measured during a zero order infusion and in blood concentrations required to maintain anaesthesia for body surface surgery.

ACKNOWLEDGEMENTS

We thank Peter Baxter for this technical assistance and ICI for donation of pure propofol.

IN VIVO DETERMINATION OF CONCENTRATION–EFFECT CURVES OF LOCAL ANAESTHETICS IN MAN

R. WIESEMES, W. KLEMENT, G. E. K. NOVOTNY AND P. LIPFERT

SUMMARY

In clinical use, the concentrations of local anaesthetics at the site of action are unknown. With the method described here, concentrations of local anaesthetics can be predetermined and kept constant at the site of action. In six volunteers, a blister was raised on the ventral surface of the forearm. After removal of the epithelium, the blister base was rinsed continuously with carbogenated Tyrode's solution with and without increasing concentrations of bupivacaine (Carbostesin) for 15 min each. The effects of bupivacaine were determined by changes in the perception (tactile sensation) of drops falling on the blister base from increasing heights. The minimal height at which the drops were just perceived characterized the threshold of perception. With increasing bupivacaine concentrations, threshold increased until the drops were no longer perceived, at a median concentration of 2.48 mmol litre^{-1} (range 1.24–3.10 mmol litre^{-1}). After the blister base was rinsed with Tyrode's solution, threshold of perception reached baseline values, which was in accordance with an intact blister base. (Br. J. Anaesth. 1993; **70**: 552–555)

KEY WORDS

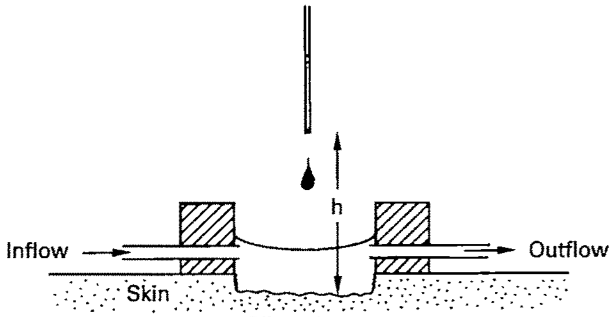
Anaesthetics, local. Pharmacodynamics: threshold concentration.

The concentrations of local anaesthetics at the site of action are unknown in clinical use [1]. Thus concentration–effect curves have been derived exclusively in animals by dissecting and bathing isolated nerves [2]. The present experiments aimed to develop a simple method in man by which concentrations of local anaesthetics could be predetermined and kept constant at the site of action. The method described here fulfilled these criteria and allowed us to test the sensitivity of neural

[redacted]

blister base was uncovered under sterile conditions, it was sealed in an open chamber (fig. 1) and rinsed continuously with carbogenated Tyrode's solution (flow 1.5 ml min^{-1}) with and without increasing concentrations of bupivacaine (Carbostesin). The solutions used were warmed to keep the blister base temperature within ±2 °C of the surrounding skin temperature as measured by infra-red telethermometry. The pH of the solutions was 7.3–7.5. The effects of bupivacaine were determined by means of changes in the perception of drops of equal size falling on the blister base from increasing heights. The minimal height at which the drops were just perceived characterized the perception threshold and was quantified by a millimetre scale connected with a support. The perception threshold was evaluated by the method of limits [4, 5]—that is, as the mean intensity of the last stimulus less than and the first greater than threshold.

After the blister base had been rinsed continuously with Tyrode's solution for 15 min, the perception threshold was evaluated in each volunteer (baseline). For this purpose, drops of the same composition were released on the blister base from increasing heights. The volunteers were asked to report if the drops touching the blister base were perceived or not. In the same way, the effect of each drug concentration was determined.



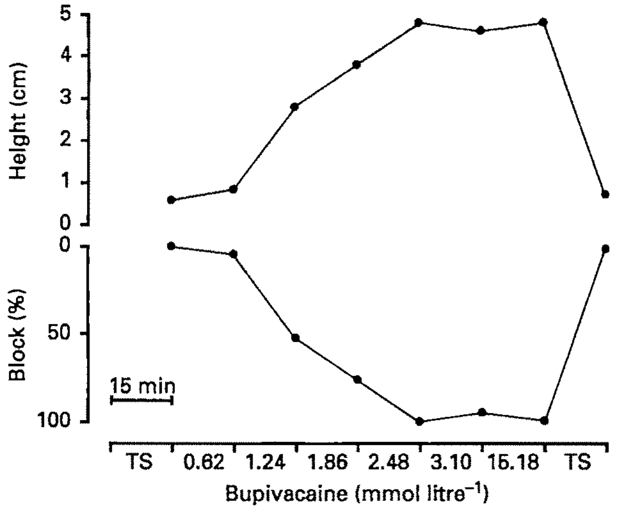


FIG. 2. A typical experimental programme. Bupivacaine concentrations were increased by 0.62 mmol and the corresponding perception thresholds (release height) evaluated (upper graph). The local anaesthetic effect of each concentration was expressed by the percent changes of perception threshold, the baseline threshold (Tyrode's solution; 0.6 cm) being set arbitrarily at 0, the threshold at maximal blocking effect (4.5 cm) at 100. Thus the blocking effects are expressed in percent of the maximal effect (relative blocking effect) (lower graph).

Starting with the smallest bupivacaine concentration (0.62 mmol litre^{-1}), the concentrations were increased stepwise. Each concentration was maintained until perception threshold repeatedly remained constant, thus demonstrating an equilibrium between the concentration at the site of action with that of the bathing solution. As the local anaesthetic effect reached a plateau within 2 min after administration, periods of 15 min for each concentration seemed to be adequate. The smallest bupivacaine concentration above which threshold remained constant was defined as the minimal blocking concentration. This definition relies on the premise that drops released from greater heights would be perceived via mechanoreceptors outside the blister base. To compare the perception threshold at the end of the experiment with the baseline value, the blister base was rinsed with Tyrode's solution again.

In one volunteer a wedge-shaped piece of the blister base and the surrounding skin was excised. It was examined to see if the epithelium was disconnected from the underlying tissues. The material was fixed by immersion in 1.25% glutaraldehyde and 1% paraformaldehyde in phosphate buffer 0.1 mol litre^{-1} at pH 7.4. Dehydration was by passage through the ascending acetone series, and the block was embedded in Spurr's medium. Semithin sections were stained with toluidine-blue.

Data analysis

Each threshold was determined four times and mean values calculated. The local anaesthetic effect was expressed by relating the percent changes in perception threshold against drug concentrations, the baseline threshold (Tyrode's solution) being arbitrarily set at 0, the threshold at maximal blocking effect at 100.

RESULTS

The results of a typical experiment are illustrated in figure 2. While the blister base was rinsed with Tyrode's solution, drops released from a height above 0.6 cm were just perceived, so that the perception threshold was 0.6 cm (upper graph). Note that the perception threshold increased as the bupivacaine concentrations increased; that is, to evoke the same minimal perception the release height had to be increased. As the perception threshold (4.5 cm) did not change with large concentrations (15.18 mmol litre^{-1}), the smallest concentration with the same threshold was defined as minimal blocking concentration (2.48 mmol litre^{-1}). At the end of the experiment, the blister base was rinsed with Tyrode's solution again, the threshold of perception being identical with baseline (0.6 cm). By relating blocking concentration of bupivacaine (X-axis) against drug effect expressed as percent of maximal

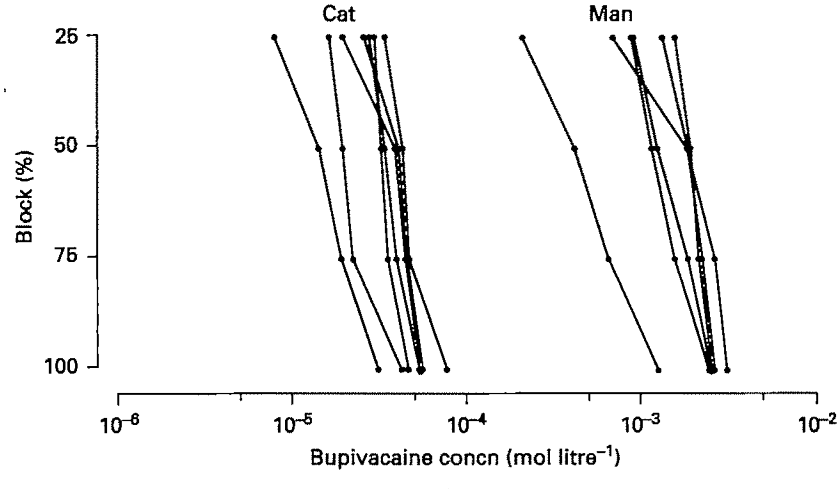

FIG. 3. Concentration–effect curves of bupivacaine derived from the blister base in man at pH 7.4 and normal skin temperature (right). The blocking concentrations for various degrees of blocking effect (75%, 50%, 25%) were interpolated, as in the experiments on the isolated aortic nerve of cats (pH 7.4, 38 °C [2]) depicted on the left for comparison. X-axis: blocking concentration (logarithmic scale); Y-axis: relative blocking effect (100 = threshold at maximal blocking effect). The concentration–effect curves are similar, but the blocking concentrations in the blister base are 45-fold greater than in the isolated nerve preparation.

effect (= relative blocking effect; *Y*-axis) a concentration–effect curve was plotted (lower graph). In each case, the drops were perceived as tactile sensation.

The individual concentration–effect curves derived from such experiments are illustrated in the right part of figure 3 (curves in the left part: see Discussion). In each experiment, the blocking effect increased in a concentration-dependent manner, the maximal blocking effects (minimal blocking concentrations) ranging from 1.24 to 3.10 mmol litre^{-1} (median 2.48 mmol litre^{-1}). For each drug concentration, a concentration equilibrium was established within 2 min. After the blister base was rinsed with Tyrode's solution, in each volunteer at the end of the experiments, perception threshold reached baseline values within 3 min. In five volunteers, the wound healed by primary intention and in one it healed by secondary intention with scar formation.

Histological examination of one blister periphery revealed that the cover of the blister consisted of epithelial layer exclusively, while the blister base was intact dermis.

DISCUSSION

The validity of our method rests on the assumption that the bupivacaine concentration in the bathing solution equals that at its site of action. Three observations support this assumption: (1) The diffusion distance between blister base and site of action was very small, as evident from anatomical and pharmacological findings. In the cantharides blister [6], the epithelium as a diffusion barrier was removed completely by uncovering the blister base. Thus mechanoreceptors sensing tactile stimuli, located at the tip of intermediate epithelial ridges and in the papillary ridges of the dermis [7, 8], are located within 100 µm from the blister base [7]. Also, the rapid establishment of plateau effects within 2–3 min (block and recovery from block, respectively) suggests diffusion distances less than 200 µm [1, 2]. That the blocking effect of bupivacaine was abolished within 3 min after the blister base was rinsed with Tyrode's solution is in accordance with earlier findings in isolated nerves [2]. The absence of an epithelial barrier and perineural binding structures may explain this rapid recovery. (2) Short diffusion distances guarantee concentration equilibrium only when more drug molecules are transported to the site of action than diffuse away. Even with maximal blood flow (8000 ml min^{-1}; [9]) in human skin (surface area 1.7 m^2), blood flow under the blister base (0.2 cm^2) is thought to be 0.1 ml min^{-1}, only a fraction of the 1.5 ml min^{-1} used in our experiments. Consequently, blister base and underlying tissues are provided with bupivacaine in abundance. (3) Although the maximal bupivacaine effect was reached within 2 (block)–3 (recovery) min, exposure time was 15 min to ensure drug equilibrium.

During generation of the blister, care was taken to keep the water temperature at 38–40 °C, as painful heat trauma should be avoided, which could sensitize and thus decrease the threshold of perception [10]. Absence of morphological damage and identical perception thresholds with Tyrode's solution before and after the blocking procedure suggest integrity of the blister base. In an effort to rank the results of the blister base method, we have compared our data with those determined in a "classical" manner—that is, in animals, by dissecting and bathing isolated nerves. As the information sensed by mechanoreceptors travels along A-fibres (conduction velocity 40–80 m s^{-1} [8]), blocking experiments in the aortic nerve of cats (A-fibres, mainly A-∂-fibres) were viewed for comparison. In these experiments [2], concentration–effect curves and minimal blocking concentrations (see left part of figure 3) were measured by bathing the nerve in increasing concentrations of bupivacaine (pH 7.4, 38 °C) and simultaneous recording of nerve activity. Surprisingly, the curves are similar in shape, and slope. Obviously, the same alterations in concentration induce the same alterations in effect characterizing similar drug–"receptor" interactions of the two preparations [11]. Also, interindividual variability does not differ, although one volunteer seemed to be conspicuously sensitive.

In contrast, however, the blocking concentrations derived from the present experiments were 45-fold greater than the minimal blocking concentrations in the aortic nerve of cats (fig. 3). Also, in experiments performed in isolated perfused vein segments of humans, the blocking concentrations were greater than in the isolated perfused nerve of the cat, by a factor of 30 [12]. There are two possible explanations for this difference:

(1) Axons are blocked, as probably occurs clinically. In this case, great blocking concentrations may be necessary because of short exposure lengths (less than three nodes of Ranvier). This assumption is based on recent experiments in isolated frog sciatic nerves [13], in which an inverse relation between blocking length and local anaesthetic concentration was found; that is, the smaller the exposure length, the greater the blocking concentration. As the nerves supplying the mechanoreceptors in the skin run perpendicularly up to the epithelium [7] and these receptors are located close to the blister base; the depth of local anaesthetic penetration into the dermis equals the exposure length of axons.

(2) Mechanoreceptors located close to the blister base and thus easily accessible for bupivacaine are blocked. As receptors are said to be less sensitive to local anaesthetics than nerve fibres (see figure 5 in [14]), they are blocked only with large concentrations. Receptor block does not seem to be involved in local anaesthesia under clinical circumstances.

I.V. BOLUS ADMINISTRATION OF SUBCONVULSIVE DOSES OF LIGNOCAINE TO CONSCIOUS SHEEP: RELATIONSHIPS BETWEEN MYOCARDIAL PHARMACOKINETICS AND PHARMACODYNAMICS

Y. F. HUANG, R. N. UPTON AND W. B. RUNCIMAN

SUMMARY

We have studied relationships between the time-courses of lignocaine concentrations in arterial and coronary sinus blood and myocardial tissue, and negative inotropic effects on the myocardium, after i.v. bolus administration of 50-, 75- or 100-mg doses of lignocaine to conscious, chronically instrumented sheep. Peak arterial and coronary sinus blood lignocaine concentrations occurred 26–38 s before and 29–78 s after the maximum decreases in myocardial contractility, respectively. Peak myocardial concentrations occurred simultaneously with the maximum decreases in myocardial contractility, except for the 100-mg doses. Anticlockwise hysteresis occurred only between arterial blood lignocaine concentrations and the negative inotropic effect. It was concluded that, after short-term i.v. administration, only the myocardial concentrations of lignocaine were in pseudoequilibrium with the negative inotropic effects of the lignocaine on the myocardium. (Br. J. Anaesth. 1993; **70**: 556–561)

KEY WORDS

Anaesthetics, local: lignocaine. Heart: myocardial drug concentration. Pharmacodynamics. Pharmacokinetics.

An assumption in many pharmacokinetic studies is that the drug concentrations in the "biophase" are proportional to, or in pseudoequilibrium with, blood drug concentrations, and that there is a simple relationship between this biophase concentration and the magnitude of the effects of the drug. While this may be true after the long-term use of drugs, in the first few minutes after short-term (i.v. bolus) drug administration (a frequent occurrence during anaesthesia) there may be a substantial lack of pseudoequilibrium between drug concentrations in blood and drug effects in the vital organs such as the heart and brain. For example, there is often an "anticlockwise hysteresis" apparent on plots of the time-course of myocardial drug effects against the time-course of the systemic (arterial or peripheral venous) blood drug concentrations after short-term drug administration, which has often been attributed to a lack of pseudoequilibrium between the drug concentrations in blood and at the receptor sites responsible for drug action in the myocardium [1–3].

It has been suggested that arterial blood drug concentration should be better indicators of the duration and potency of drug effects because arterial blood carries drug to the sites of effect [4, 5]. Alternatively, the use of local venous blood drug concentrations has been proposed because these should be in pseudoequilibrium with tissue concentrations [4, 5]. It has also been proposed that drug concentrations at the receptor sites of a tissue should be in continuous equilibrium with drug concentrations in that tissue [6], and the magnitudes of drug effects on the myocardium therefore should be a function of the myocardial drug concentrations [7]. However, these relationships between drug concentrations in arterial or venous blood or the myocardium and drug effects on the heart after short-term i.v. drug administration are still uncertain.

This study compared the time-courses of the depression of myocardial contractility caused by i.v. bolus doses of lignocaine [8] with the simultaneously measured time-courses of its concentrations in arterial and coronary sinus blood, and in the myocardium determined using mass balance principles [9], in a chronically instrumented sheep preparation. The aim was therefore to determine which, if any, of these concentrations is related directly to the myocardial contractility depression induced by lignocaine. When this concentration has been identified, a knowledge of the determinants of its time-course may be used to explore avenues for optimizing the initial time-course of the myocardial effects of lignocaine.

MATERIALS AND METHODS

In this paper, aspects of the pharmacodynamic [8] and pharmacokinetic [9] data arising from a series of studies in five chronically instrumented adult female merino sheep are analysed and compared in detail.

Relevant details of methods used in those studies [8, 9] are summarized here.

Sheep preparation

Sheep were prepared under anaesthesia (thiopentone for induction, 1.5% halothane for maintenance) with catheters in the ascending aorta, coronary sinus and inferior vena cava (IVC) via the carotid artery or jugular vein [8, 9]. An ultrasonic Doppler flow probe was placed on the left main coronary artery for measuring blood flow in this vessel [9]. A gas-powered system kept the intravascular catheters flushed with heparinized saline. Studies were conducted 1 week after the surgical preparations and at 2-day intervals thereafter while the sheep remained in their cages with free access to food and water.

Study design

Lignocaine hydrochloride in doses of 50, 75 or 100 mg was diluted to 10 ml with 0.9% saline immediately before each experiment. After a period of baseline haemodynamic measurements, a randomly selected dose was injected i.v. via the IVC catheter over 1 s [8, 9]. Pharmacodynamic and pharmacokinetic measurements were made for the next 15 min. The 50-, 75- and 100-mg doses of lignocaine were studied in five, four and five sheep, respectively.

Pharmacodynamic measurements. Left coronary artery blood flow velocity was measured continuously using an ultrasonic Doppler flowmeter and the Doppler flow probe placed on the left main coronary artery [9]. The maximum rate of increase in left ventricular pressure (LV dP/dt_{max}), used as an index of myocardial contractility, was obtained from the differentiated left ventricular pressure, which was measured continuously using a Millar Mikro-Tip pressure transducer catheter (Millar Instruments Inc., Houston, Texas, U.S.A.) placed in the left ventricle via one of the arterial catheters before each experiment [9].

Pharmacokinetic measurements. Paired blood samples were collected from the ascending aorta and the coronary sinus at up to 5-s intervals for 15 min after drug administration, using the sampling methods described previously [8, 10]. All samples were stored at −20 °C and the whole blood concentrations of lignocaine were assayed using a single extraction gas chromatographic method [11]. These concentrations and left coronary blood flow were used to calculate the time-courses of lignocaine concentrations in the myocardium perfused by the left coronary artery using mass balance principles. This method calculates the time-course of the myocardial drug concentrations from the net difference in flux of drug in the afferent (arterial) and efferent (coronary sinus) blood; its application to the myocardium has been described in detail previously [9, 12].

Data and statistical analysis

The following comparisons were made between the time-courses of the concentrations of lignocaine in arterial and coronary sinus blood and the myocardium, and the time-courses of the depression of myocardial contractility.

(1) The times of the peak arterial blood, coronary sinus blood or calculated myocardial lignocaine concentrations were compared with the times of the maximum depression of myocardial contractility. Note that the maximum depression of myocardial contractility described here refers to the observed maximum decrease in LV dP/dt_{max} under conditions of non-steady-state blood drug concentration (fig. 1).

(2) Lignocaine concentrations in the arterial blood, coronary sinus blood or the myocardium were plotted in time order against the percent decreases in myocardial contractility induced by lignocaine to examine for hysteresis and non-linearity in the concentration–effect relationships. If there was a time lag between concentration and effect (e.g. hysteresis), the plots were not superimposible and showed a clockwise or anticlockwise loop. To quantify the magnitude of hysteresis, each plot was divided into two sections at the point of the peak lignocaine concentration so that one section represented concentration–effect relationships when lignocaine concentrations were increasing, and the other represented the relationships when the lignocaine concentrations were decreasing. The area under each section of the curve (AUC) was calculated using the trapezoidal rule. Hysteresis was considered to be present when the differences between the AUC of these two sections of the hysteresis loop were statistically significant.

Two-sample *t* tests were used for the analysis of the AUC of the two sections of the hysteresis loops and the differences between the times of peak lignocaine concentrations and the times of maximum drug effect. Linear regression was used to correlate myocardial lignocaine concentrations and the percent decreases in myocardial contractility (LV dP/dt_{max}). $P < 0.05$ was considered statistically significant.

RESULTS

These subconvulsive doses of lignocaine induced significant and dose-dependent negative inotropic effects on the myocardium, as indicated by the decreases in LV dP/dt_{max}, in the absence of significant changes in heart rate or mean arterial pressure [8]. During the 15 min period after lignocaine administration, there was substantial lack of pseudoequilibrium between the myocardial lignocaine concentrations calculated using mass balance principles and lignocaine concentrations measured in arterial or coronary sinus blood [9]. The raw data for all the three dose groups are summarized in figure 1.

The times of the peak lignocaine concentrations in arterial blood, coronary sinus blood and myocardium are listed in table I. For all the doses, the times of the peak arterial blood lignocaine concentrations were approximately 26–38 s earlier than the times of maximum decreases in myocardial contractility. The times of the peak coronary sinus blood lignocaine concentrations were approximately 29–78 s later than the times of maximum decreases of myocardial contractility. With the exception of the 100-mg

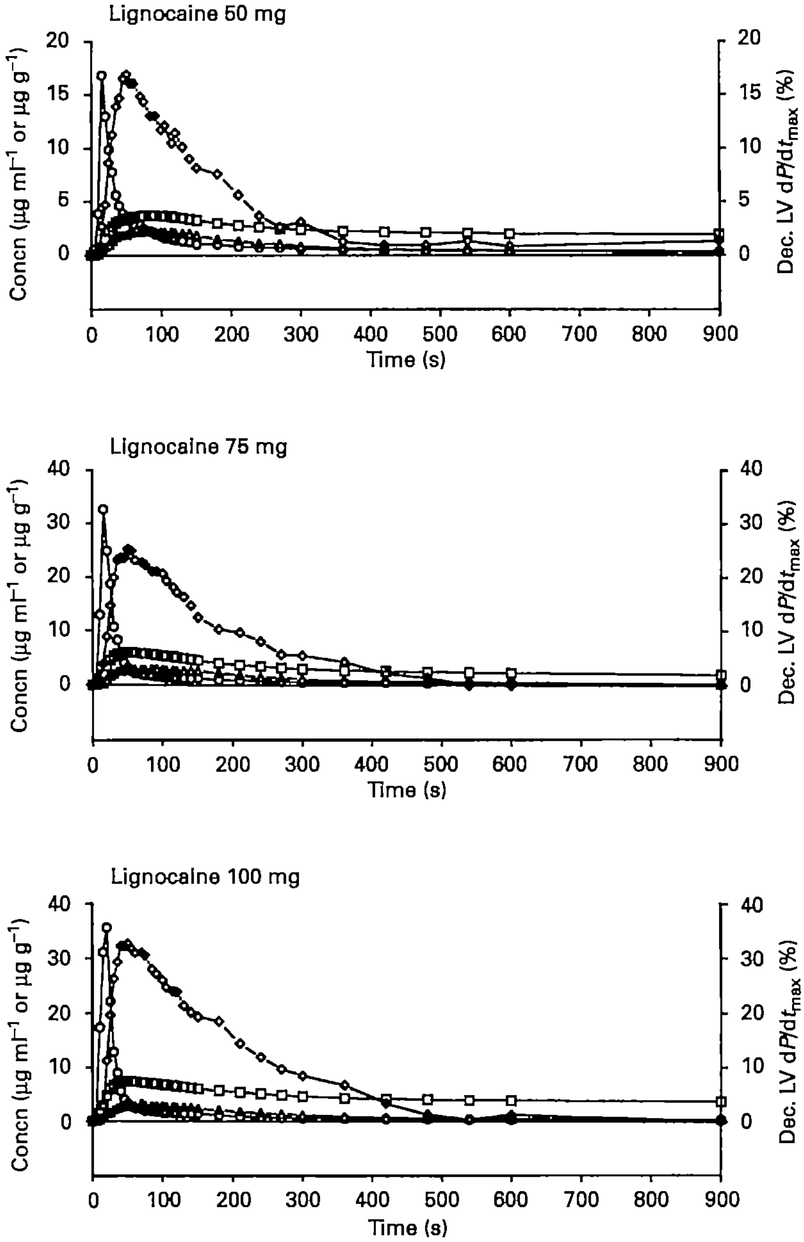

FIG. 1. Mean time-courses of lignocaine concentrations in arterial blood (○), coronary sinus blood (△) and the myocardium (□) (vertical axis at left) and the time-courses of the percent decreases (Dec.) in myocardial contractility (LV dP/dt_{max}) (◇) (vertical axis at right) from baseline after the 50- ($n = 5$), 75- ($n = 4$) and 100- ($n = 5$) mg doses of lignocaine.

doses of lignocaine, the times of the calculated peak myocardial lignocaine concentrations did not differ from the times of the maximum decreases in myocardial contractility (table I). For the 100-mg doses, the mean time of the peak lignocaine myocardial concentrations was 17 s later than the mean time of maximum myocardial contractility depression.

Examples of the percent decreases in LV dP/dt_{max} plotted against lignocaine concentrations in the arterial and coronary sinus blood and the myocardium after i.v. injection of 100-mg doses are shown in figure 2. The differences between the AUC under the sections when lignocaine concentrations were increasing and the sections when lignocaine concentrations were decreasing in the concentration–effect curves for the three doses are shown in table II. Significant anticlockwise hysteresis was present between the arterial lignocaine concentrations and the decreases of myocardial contractility in each dose group. No significant hysteresis was found between the coronary sinus blood lignocaine concentrations or the calculated myocardial lignocaine concentrations and the decreases of myocardial contractility.

A linear pharmacodynamic model [2, 13] was used to describe the myocardial lignocaine concentration–effect relationships. The data for the three doses were pooled together for this analysis. Linear regression between the myocardial lignocaine concentrations and the percent decreases of LV dP/dt_{max} were performed (fig. 3). The correlation coefficient (r) between myocardial lignocaine concentrations and the percent decreases in LV dP/dt_{max}

Myocardial concentration–effect	0.17 (0.26)	0.14 (0.14)	0.36 (0.24)

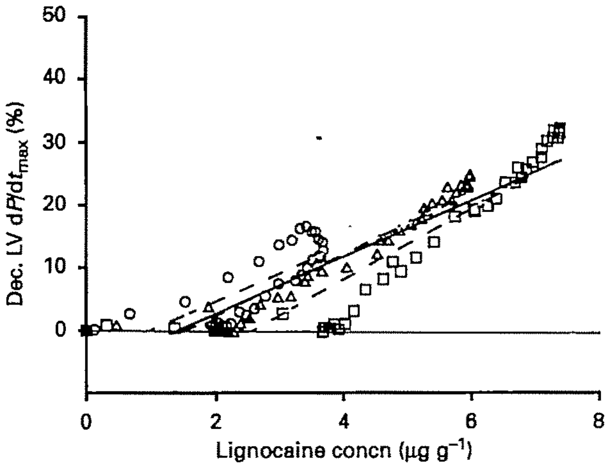

FIG. 3. Linear regressions between the mean myocardial concentrations of lignocaine and percent decrease in myocardial contractility (LV dP/dt_{max}). ○ = Lignocaine 50 mg; △ = lignocaine 75 mg; □ = lignocaine 100 mg. Dashed lines are the linear regressions for each dose group. Solid line is the linear regression for the pooled data of all the doses with an intercept of −4.45, slope of 4.44 and correlation coefficient 0.92.

was 0.92. The slope of this correlation was 4.4 and the intercept −4.5. Linear regression between myocardial lignocaine concentrations and the percent decreases in LV dP/dt_{max} also was performed for each dose group. The mean (SD) of the slopes of the 50-, 75- and 100-mg groups were 4.5 (2.7), 6.0 (2.4) and 5.7 (2.7), respectively. There was no significant difference among the individual slopes.

DISCUSSION

The technical difficulties of measuring myocardial drug concentrations in conscious animals without perturbing myocardial function have presumably contributed to the use of compartmental pharmacokinetic and pharmacodynamic models to describe and predict the relationship between myocardial drug kinetics and dynamics, because these models can be developed on the basis of blood drug concentration data [14]. Alternatively, the theoretical receptor site drug concentrations can be modelled using "effect compartment" pharmacokinetic and pharmacodynamic models such as those reported in the study of tubocurarine and thiopentone [15, 16]. In these models, the "receptor site" drug kinetics were linked to the central compartment by a first-order rate constant which was adjusted empirically so that hysteresis between drug concentrations at the receptor sites and drug effect disappeared. Although these models offer some resolution to the problem of hysteresis, their significance is limited by their lack of physiological reality [17]. In this study, lignocaine concentrations were measured or calculated at three sites relevant to myocardial drug kinetics and dynamics: arterial blood, coronary sinus blood and myocardium. Their usefulness in predicting drug effect is discussed in turn.

A poor relationship between the arterial blood concentrations of lignocaine and the decreases in myocardial contractility was shown by the differences between the times of the maximum decreases in myocardial contractility and the times of peak arterial blood concentrations of lignocaine (table I), and the *anticlockwise* hysteresis of the concentration–contractility relationships (fig. 2, table II), which suggests that these effects lag behind the arterial drug concentrations. Similar hysteresis between the arterial plasma concentrations of propofol, procainamide, lignocaine and their depressant effects on myocardial contractility after short term i.v. administration have also been reported [3, 18, 19]. The myocardial effects of some general anaesthetics were found to be poorly correlated with blood drug concentrations [20]. The lack of pseudoequilibrium between arterial blood and myocardial lignocaine concentrations reported in previous studies is the most likely explanation for these observations [9].

From the argument of Horowitz and Powell [21], it would be anticipated that the lignocaine concentrations in the myocardium would be better indices of the myocardial effects than its arterial concentrations. However, it should be remembered that methods based on mass balance principles determine the mean myocardial drug concentration, which may in itself be inadequate if the drug acts on specific sites of the myocardial cells that are not in pseudoequilibrium with the mean tissue concentration shortly after an i.v. bolus. Nevertheless, for all the doses used, good correlations were found between the myocardial lignocaine concentrations and the depression of myocardial contractility, with no significant hysteresis in the concentration–effect plots (table II, fig. 2). This provides evidence that lignocaine concentrations at the receptor sites responsible for the decrease of myocardial contractility were in pseudoequilibrium with the measured myocardial lignocaine concentrations [6].

A saturable concentration–effect curve was not observed in this study. However, during the first 20–30 s after lignocaine injection (represented by the first four points on the curve in figure 3), the myocardial lignocaine concentration–effect plots appear to curve upwards. After this period, the concentration–effect relationship was essentially linear. Because neither the concentrations nor the effects of lignocaine reached steady-state or their maximum values in this study, a linear pharmacodynamic model was used to describe the myocardial lignocaine concentration–effect relationship (fig. 3).

Myocardial drug concentrations are relatively difficult to monitor in patients [7]. As a simpler alternative, the effluent regional venous blood from the tissue or organ in which a drug exerts its effects could be used for the study of regional pharmacodynamics [4, 5]. This is an extension of the concept of venous equilibrium used in many physiological pharmacokinetic models in which the tissue and the effluent venous drug concentrations were related by a constant ratio—the partition coefficient. In this study, the coronary sinus blood concentrations of lignocaine were related relatively closely to the myocardial depressant effects (fig. 2, table II). However, the times of peak coronary sinus blood lignocaine concentrations were significantly later than the times of the maximum depression of myocardial contractility induced by lignocaine (table I). In this sense, the coronary sinus blood concentrations of lignocaine were not in equilibrium with the negative inotropic effects on the myocardium and therefore were not equivalent to the calculated myocardial concentrations of lignocaine, at least after such rapid i.v. drug administration. It would be expected that, in situations in which the blood drug concentration changes are slower than those which occur after i.v. bolus administration, the use of regional venous blood concentrations as indices of drug effect may have some merit, although a thorough knowledge of the relationships between regional venous and tissue drug concentrations would be an important prerequisite [22].

ACKNOWLEDGEMENTS

This study was supported by a grant from the National Heart Foundation of Australia. The authors thank Professor L. E. Mather for providing research facilities in the Department of Anaesthesia and Intensive Care of Flinders Medical Centre while those at the University of Adelaide were being refurbished. The authors also thank Dr J. P. Plummer for his statistical advice. Technical help from Mr K. Smart, Ms E. Henning and Ms C. Adcock is greatly appreciated.

REVIEW ARTICLE

THE MANAGEMENT OF ACUTE POISONING

G. G. COLLEE AND G. C. HANSON

Self poisoning is among the most common causes of non-traumatic coma in patients younger than 35 yr, and accounts for approximately 10% of all acute medical admissions [8]. Anaesthetists may become involved in the care of these patients during emergency resuscitation or in the intensive care unit. In the U.S.A., acute self poisoning accounts for 5–30% of admissions to medical intensive care units [21, 23].

Classification

Self-poisoning accounts for 95% of all poison-related admissions. It is slightly commoner in females (female to male ratio approximately = 1.3:1) with a peak incidence in females younger than 25 yr, and between 20 and 35 yr for males [8]. About 50% of all overdoses involve a mixture of agents [8, 10, 21]. Self-poisoning is often an impulsive act with no clear intent to die and with a previous history of similar episodes [33].

Accidental poisoning occurs predominantly in children younger than 5 yr, and may be with medicines (usually those prescribed to a parent) or household products. Each year accidental poisoning in children accounts for about 24000 hospital admissions in England and Wales [5]. Only about 15% of the children presented to hospital with accidental poisoning develop symptoms from the agent ingested [23]. Fatal accidental poisoning is rare [35].

Non-accidental poisoning may occur as an extension of the syndrome of child abuse, usually in children younger than 30 months. This may be more common than is generally accepted [7], and has a fatal outcome more commonly than cases of accidental poisoning [23].

Homicidal poisoning is encountered rarely in clinical practice.

Diagnosis

Diagnosis is usually made from the history and circumstantial evidence. However, patients' statements about the nature and the quantity of the poison ingested are unreliable [39]. Witnesses, family, friends and ambulance personnel should be interviewed to establish details regarding the probable agents ingested and approximate time of ingestion. Alcohol is often taken in combination with one or more other agents.

Isolated signs and symptoms are of little diagnostic value in any poisoning incident, but identification of the agent can often be surmised from the history and examination. Various combinations of signs may be suggestive of specific commonly ingested poisons [11]; however, there is a poor correlation between drugs suspected on admission and those actually detected in the blood [21]. The agents used in deliberate self-poisoning undergo changing patterns, with various agents going in and out of vogue. Currently in the U.K., the agents encountered most commonly in deliberate self-poisoning are the benzodiazepines, paracetamol, aspirin and tricyclic antidepressants [8]. Car exhaust poisoning is the method of suicide used most often by men aged 15–44 yr [29].

Toxicological screening should be considered in the urgent investigation of coma when the history, examination and biochemical analysis do not yield a diagnosis. About 50% of patients attending a casualty department with coma of unknown aetiology may be self-poisoning cases [10]. Appropriate samples should be collected early in the initial management of these patients so that they are available later if required for either diagnostic or medico–legal purposes. These samples should include:

Gastric contents: 50 ml of vomit, aspirate or the first portion of a gastric lavage.

Urine: 50 ml of the first sample voided after admission.

Blood: 10 ml of lithium–heparinized blood, 10 ml of blood without anticoagulant, and 2 ml of fluorided blood for ethanol assay. Care should be taken to avoid the use of swabs containing alcohol.

Ideally, all of these samples should be collected before administration of any medications which may confuse toxicological analysis.

Routine biochemical and haematological investigations may, rarely, suggest a diagnosis of acute poisoning. More often they provide a helpful baseline for later comparison. Many poisons cause fluid and electrolyte imbalance, renal or hepatic impairment, or acid–base imbalance.

The majority of patients admitted after acute

poisoning are conscious on arrival at the hospital; however, in unconscious patients organic brain damage should always be suspected if the history of poisoning is unsatisfactory and the depth of coma does not improve within 12 h.

MANAGEMENT

Before consideration of the active management of the poisoned patient, it should be emphasized that, for the majority of poisoned patients, only supportive care is needed. This led one reviewer to comment "It cannot be repeated too often that the primary object of the treatment of acute poisoning is not to collect as much 'poison' from the patient as possible, but to save life when this is threatened and to relieve pain and suffering... i.e.... to save the patient, not to regain the poison" [22].

Immediate measures

Initial resuscitation in comatose patients should be conducted with the usual priorities: A–B–C–D–E:

Airway. Provide one if the patient's upper airway is obstructed. Protect the airway if the cough and gag reflexes are obtunded and secure the airway, when necessary, with tracheal intubation (this may include patients with marginally adequate protective reflexes who require gastric lavage).

Breathing. Assess the ventilatory efforts and assist where necessary. Assess gas exchange. Look for evidence of aspiration of gastric contents, toxic gases or foreign substances.

Circulation. Establish i.v. access early. Assess peripheral perfusion and begin resuscitation as required. Connect electrocardiographic monitoring and examine a rhythm strip.

Collect samples for future toxicological analysis if required.

Document the available history before ambulance personnel, relatives, etc. leave the hospital, and the level of coma.

Examine the patient thoroughly for associated injuries (e.g. pressure area necrosis), medical conditions which may have precipitated the overdose (e.g. toxic psychosis) or which may produce coma (e.g. hypoglycaemia).

Measures to limit absorption

The conventional belief that, after ingestion of poisons other than corrosives or petroleum distillates, the stomach should be routinely emptied by emesis or gastric lavage has been questioned by several authors [25, 27, 37].

Emesis should be induced only in fully conscious patients. It is less traumatic for the conscious patient than gastric lavage and is therefore the preferred technique of gastric emptying for children. However, the recovery of gastric contents by ipecacuanha-induced emesis is generally less than 50% [28, 37]. Syrup of ipecacuanha followed by an adequate volume of water induces vomiting in 90–95% of patients within 20–30 min, in both adults and children [13, 32]. Evidence that this emesis significantly reduces the absorption of commonly ingested poisons is less convincing. Therefore, although it only rarely causes serious sequelae, it is probably of little or no benefit to the majority of poisoned patients. The decision to empty the conscious patient's stomach by inducing emesis should be dependent upon the specific history of probable toxins, the estimated dose and the time since ingestion, rather than an automatic response to a history of acute poisoning.

Gastric aspiration and lavage is the only suitable way of emptying the stomach in the presence of obtunded laryngeal and pharyngeal reflexes. Airway protection is an essential part of the procedure. In the semi-conscious patient, airway protection may be achieved by placing the patient in the left-lateral, head-down position in the presence of an experienced anaesthetist with suction apparatus immediately to hand. In patients with more severely obtunded reflexes, it is safer to opt for elective tracheal intubation before gastric lavage.

Gastric aspiration and lavage via a wide-bore orogastric tube is indicated within 4 h of serious poisoning (i.e. the patient is comatose) with any of the commonly ingested poisons. The technique has been well described elsewhere [26]. Because the history is usually unreliable and gastric emptying is delayed by many poisons (notably aspirin and the tricyclic antidepressants), gastric lavage should be considered in any seriously poisoned patient up to 12 h after ingestion [12]. Conversely, with drugs which do not delay gastric emptying and which are absorbed rapidly from the gastrointestinal tract (e.g. paracetamol), gastric lavage may be ineffective as little as 2–4 h after ingestion.

Activated charcoal is a powerful, non-specific adsorbent which may be administered orally or via a gastric tube. Irreversibly binding the drugs within the bowel reduces blood concentration both by reducing drug absorption and by creating a negative diffusion gradient between the gut lumen and the blood, whereby drug diffuses from the circulation into the gut lumen—so called "gastrointestinal dialysis" [18]. It may be appropriate, therefore, to administer activated charcoal long after the original poisoning, and repeated administration is advocated as a safe, cheap and effective method of reducing drug concentrations in the blood. It is of demonstrable benefit after poisoning with several commonly ingested drugs, including aspirin [20] and paracetamol [19]. Anecdotal reports support the use of repeated administration of activated charcoal after a variety of other poisons. Enthusiasm for these relatively unproven uses, however, must be tempered by reports of serious consequences of pulmonary aspiration of activated charcoal [9, 24] and the minor risk of gastrointestinal obstruction after its use [36]. Furthermore, there are theoretical limitations. Drug elimination with activated charcoal is less effective in patients with severely impaired gastrointestinal motility—particularly relevant after poisoning with salicylates or with agents which have a significant anticholinergic action. Kirshenbaum and colleagues have questioned the clinical efficacy of multiple-dose charcoal therapy after salicylate poisoning [16]. It is suggested also that clearance of parenterally administered medications used to treat intoxicated patients is increased by the charcoal, perhaps making treatment less effective.

Further pharmacokinetic data on the clearance of specific poisons are needed to determine the rational use of repeated charcoal regimens in a variety of clinical settings. Meanwhile, it provides a relatively safe technique of proven benefit in limiting drug absorption when given soon after ingestion of specific poisons. It is also probably of benefit in repeated doses in carefully selected clinical circumstances. Drugs which are well adsorbed to activated charcoal include benzodiazepines, antidepressants, anticonvulsants, barbiturates and theophylline. Salicylates and paracetamol are moderately well adsorbed.

Supportive care

All but a small minority of unconscious poisoned patients recover with supportive care alone. Conservative therapy is aimed at preventing complications such as hypoxaemia, aspiration, hypotension, acid–base and electrolyte imbalance, hypothermia, convulsions and the consequences of unconsciousness, whilst awaiting spontaneous elimination of the poison via the liver, kidneys, lungs and gut.

Respiratory complications are the commonest causes of death after acute poisoning, and immediate management must give priority to the airway, ventilation and prevention of aspiration. Having established an airway, it is important to assess the protective reflexes and consider the need for tracheal intubation. Whether or not gastric lavage is considered appropriate, a nasogastric tube should be inserted to prevent gastric dilatation. Hypoventilation is common after poisoning with sedatives, hypnotics, analgesics and many other drugs and chemicals. Hypoxia and hypercapnia may cause or potentiate cardiac arrhythmias or may exacerbate increased intracranial pressure, and should therefore be treated promptly. Specific antidotes may play a role in reducing the need for mechanical ventilation after poisoning with opioids or benzodiazepines (see *Neurological complications*).

Continued observation is essential in order to detect deterioration in the conscious level requiring a reappraisal of the need for airway protection or mechanical ventilation. Nurses should be given *specific* criteria by which to assess the need for re-referral to an anaesthetist. All patients requiring mechanical ventilation or tracheal intubation should be transferred to an intensive care unit for further monitoring.

Patients may present after long periods of respiratory depression, having already developed aspiration pneumonia or hypostatic pneumonia. The mainstay of treatment comprises endobronchial aspiration, physiotherapy and antibiotics.

Cardiovascular complications include hypotension, cardiac arrhythmias and cardiac arrest. A careful assessment of the patient's cardiovascular status should be made soon after presentation. The major factors contributing to hypotension in the presence of normal sinus rhythm are peripheral vasodilatation and myocardial depression, and the majority of patients respond to adequate intravascular volume repletion. In young, previously healthy patients, invasive monitoring is rarely required.

Arrhythmias may be caused by the toxin (e.g. poisoning with tricyclic antidepressants), hypoxia or hypercapnia, or may be secondary to the effects of the toxin on acid–base or electrolyte balance. A 12-lead ECG should be performed to provide a baseline and, in selected patients, continuous ECG monitoring is required. Patients suffering cardiac arrest as a direct result of a circulating toxin may be resistant to attempts to re-establish sinus rhythm. It is therefore worth persisting with external cardiac massage for longer than may otherwise be considered appropriate. Particular caution should be exercised in attributing any significance to the presence of fixed dilated pupils, which may reflect merely the actions of the toxin rather than any cerebral dysfunction.

Renal complications may result from the direct effects of the toxin (e.g. in aspirin, paracetamol or heavy metal poisoning), from a period of hypotension, from rhabdomyolysis with myoglobinuria, or from sepsis related to aspiration pneumonia. For further information beyond the scope of this article, the reader is referred to an extensive review of nephrotoxins by Abuelo [1].

Myoglobinuria should be suspected in any patient with evidence of a prolonged period of coma before admission (i.e. pressure area discolouration with poor capillary refill), with a history of prolonged seizures or with tissue hypoxia (e.g. from carbon monoxide poisoning).

Any comatose or hypotensive patient, or any patient with a history of poisoning with a known nephrotoxin, should be catheterized, and the urine output maintained at least at 0.5 ml kg^{-1} h^{-1}. This is achieved with volume resuscitation in the first instance followed, if necessary, by an infusion of dopamine in a small dose (2–4 μg kg^{-1} min^{-1}) and the judicious use of diuretics. Urinalysis before intervention may aid diagnosis by pointing to a renal or pre-renal cause, and occasionally by displaying the granular casts of acute tubular necrosis or the eosinophils of an acute interstitial nephritis.

When rhabdomyolysis is suspected, urinalysis of myoglobin should be performed, but treatment should be started promptly without awaiting the results of urinalysis. Urine output should be maintained at least at 1.5–2 ml kg^{-1} h^{-1} with aggressive volume loading and mannitol, and the urinary pH should be kept greater than 6.5 in order to prevent myoglobin from precipitating in the renal tubules. Loop diuretics have the theoretical disadvantage of acidifying the urine, therefore mannitol is preferred for maintaining the diuresis. Blood samples should be taken for measurement of the urea, creatinine, potassium, calcium and creatine phosphokinase concentrations. In severe cases, hypocalcaemia may result from a shift of extracellular calcium into injured muscle. Serum potassium concentrations may increase rapidly because of muscle breakdown, necessitating early intervention with calcium, glucose and insulin infusion, or dialysis.

Hepatic and gastrointestinal complications. Gastric stasis may occur in any comatose patient, or in response to anticholinergic or opioid effects. Early decompression with a nasogastric tube should be performed to reduce the risk of regurgitation and aspiration. Stress ulcer prophylaxis may also be appropriate in selected patients.

Fulminant hepatic failure is a well recognized complication of serious poisoning with paracetamol, carbon tetrachloride or *Amanita phalloides.* These patients require early referral to a specialist liver unit.

Neurological complications include depression of conscious level, seizures, cerebral oedema and peripheral nerve injuries as a result of prolonged pressure. It is important to exclude metabolic or traumatic causes, and any patient whose level of consciousness appears inappropriately depressed for the history of poisoning should be suspected of having an intracranial haemorrhage. Lateralizing signs are rarely attributable directly to the toxin.

Correct nursing care is essential to protect the patient from the complications of prolonged coma. The presence of pressure area necrosis, neuropraxias, corneal abrasions and other sequelae of coma must be documented on admission to the unit, both to alert the nurses to areas requiring special attention, and to provide medico–legal protection. The role of specific antagonists such as naloxone and flumazenil to antagonize central nervous system depression is controversial [2]. Reversal of coma can undoubtedly make management of the patient easier; however, acute antagonism of opioids with naloxone, or of benzodiazepines with flumazenil, may provoke severe withdrawal reactions. Antagonism of benzodiazepines with the specific antagonist, flumazenil, may be counterproductive in patients who have taken a mixture of drugs. For example, in the commonly encountered poisoning with both tricyclic antidepressants and benzodiazepines, acute antagonism of the benzodiazepines may induce seizures which had previously been suppressed. Moreover, for both antagonists the action of the antagonism is short-lived, therefore the patient may become comatose unexpectedly as the antagonist wears off.

Seizures may result from metabolic disturbance, cerebral hypoxia, or as a direct toxic effect (e.g. after poisoning with tricyclic antidepressants or theophylline). Urgent control is essential and is usually achieved initially with i.v. diazepam. Thereafter, consideration must be given to further anticonvulsant therapy (e.g. with phenytoin, phenobarbitone or clonazepam). Resistant subjects may require an infusion of thiopentone. Some of these agents cause further respiratory depression and elective tracheal intubation and artificial ventilation may be necessary. Detection of further seizures may be difficult in the patient undergoing ventilation, and monitoring should include continuous recording with a cerebral function monitor if neuromuscular blockers are used.

Cerebral oedema should be anticipated in any patient who has suffered a hypoxic cardiac arrest, a period of profound hypotension or severe carbon monoxide poisoning. Treatment to prevent secondary brain injury should include elective intubation and mechanical ventilation to moderate hypocapnia, with careful control of cerebral perfusion pressure by maintaining the mean arterial pressure within the normal range for that patient, and by avoiding fluid overload. Mannitol and loop diuretics may have a role after specialist consultation, and in severe cases intracranial pressure monitoring may be appropriate to direct therapy.

Metabolic complications may take almost any form in acute poisoning. The concentrations of urea, electrolytes and blood glucose should be checked routinely. In some patients, blood-gas analysis is also required.

Hypothermia is a common complication of prolonged coma outside hospital, and may be exacerbated by drugs which prevent the usual responses of vasoconstriction and shivering. Passive rewarming should be achieved with warm blankets. Active external rewarming is discouraged, as it may produce peripheral vasodilatation when cardiac function is still depressed by a reduced core temperature. I.v. fluids should be warmed and, during artificial ventilation, warm water bath humidifiers should be added to the breathing system. In extreme cases (< 32 °C) resistant to these techniques, it may be necessary to rewarm actively with warm water gastric or bladder instillation or by peritoneal lavage. Temperature should be monitored centrally (oesophageal or nasopharyngeal) and the ECG should be monitored for arrhythmias.

Hyperthermia may occur in acute intoxication with, for example, tricyclic antidepressants, cocaine or amphetamines, or as part of the syndrome of neuroleptic malignant syndrome after phenothiazine overdosage. In severe cases, active cooling with sedation, paralysis and ventilation with unheated gases may be required to control core temperature.

Measures to enhance elimination of the poison

Fewer than 5% of cases of acute poisoning merit treatment with specific techniques to increase drug elimination [34]. "*Gastrointestinal dialysis*" with activated charcoal has already been discussed, and for those drugs which are readily adsorbed to activated charcoal it provides the safest mechanism of enhancing drug clearance. More invasive techniques are rarely justified. In cases of serious poisoning, specialist advice should be sought from the regional poisons centre.

Forced diuresis should be considered only for those patients in whom toxicological analysis has demonstrated the presence in the blood of a toxic agent in sufficient amount to cause severe poisoning. Brisk diuresis maintains a small concentration gradient between the renal tubular fluid and the renal capillary bed, thereby minimizing tubular reabsorption of toxins. Manipulation of the urinary pH may further decrease tubular reabsorption of the targeted drug by ensuring that it remains mostly in the ionized form. Therefore, for weak acids (such as salicylates or barbiturates), forced alkaline diuresis is most effective, whilst for weak bases (such as phencyclidine) forced acid diuresis is more appropriate. The technique is ineffective for drugs which are strongly protein-bound (e.g. tricyclic antidepressants, carbamazepine, phenytoin) or which have a large apparent volume of distribution (e.g. paracetamol, lithium, tricylic antidepressants). Regimens to establish a forced alkaline or forced acid diuresis have been described well elsewhere [34]. The technique, however, carries significant risk of causing fluid overload with pulmonary oedema or cerebral oedema, or of causing severe disturbance of electrolyte and acid–base balance. This risk is accentuated in the elderly, or those with cardiac or renal impairment, and should be balanced against the likelihood of significantly altering the patient's clinical outcome.

Extracorporeal elimination techniques—haemodialysis and haemoperfusion—have not yet been assessed adequately clinically in acute poisoning, and there remain many difficulties in assessing the efficacy of these invasive techniques [4, 38]. Their use should currently be limited to a carefully selected group of patients, and specialist help should always be sought. For extracorporeal elimination techniques to be helpful the following criteria are suggested [4]:
(1) The drug or toxin should either diffuse readily through the dialysis membrane or be readily taken up by an absorbant. Protein-bound drugs and large molecules are removed inefficiently by dialysis, and can be removed more effectively by haemoperfusion (in which the blood is passed directly over sorbent particles to which toxins or drugs are adsorbed by surface forces). However, although salicylates are protein-bound, the plasma binding sites are saturated quickly even at normal therapeutic plasma concentrations, therefore a large proportion of the drug exists in the unbound form.
(2) A significant proportion of the poison should be present in the plasma water, or be capable of rapid equilibration with it. Drugs with a large volume of distribution and high lipid solubility are therefore difficult to eliminate. If movement of the drug from the extravascular compartment back into the intravascular compartment is slower than the plasma clearance achieved, a rebound of the plasma concentration occurs on stopping dialysis/haemoperfusion.
(3) The pharmacological effect of the toxin should be directly related to its concentration in the blood.
(4) Dialysis or haemoperfusion should add significantly to other body mechanisms of elimination.

Peritoneal dialysis achieves considerably less clearance of plasma than can be achieved with haemodialysis, and has no established role in the management of acute poisoning.

Haemodialysis or haemoperfusion has a clearly established role in the treatment of severe salicylate overdosage or poisoning with death cap mushrooms (*Amanita phalloides*) [4]. Clearance of alcohol, ethanol, barbiturates, anticonvulsants, benzodiazepines, lithium, cardiac glycosides and many other less commonly encountered poisons can certainly be enhanced with extracorporeal techniques; however, it remains unclear if this influences clinical outcome favourably. Clearance of paracetamol and the tricyclic antidepressants is not enhanced by haemodialysis or haemoperfusion, and extracorporeal elimination techniques have no role in the management of patients after poisoning with these agents.

Use of specific antidotes

The toxic effects after poisoning with specific agents may be decreased or prevented by administration of their specific antidotes. Such antidotes may directly influence the metabolism of the poison, preventing or reducing the formation of harmful metabolites (e.g. acetylcysteine in paracetamol poisoning), may compete for drug receptor sites (e.g. flumazenil in benzodiazepine overdose; naloxone in opioid overdose) or may bind with the poison to form less toxic chelates which are more easily excreted (e.g. Fab fragments in severe cardiac glycoside overdosage). A broader definition of an antidote includes any substance which can favourably influence the onset, severity or duration of the toxic effects of a poison. The currently available antidote therapies and their clinical use has recently been reviewed comprehensively by Lheureux, Even-Adin and Askenasi [17] and emergency departments should keep a reference list of antidotes and their mode of administration for quick reference.

FEATURES AND TREATMENT OF SPECIFIC POISONS

It is proposed not to give here detailed aspects of management, but to provide a ready, practical referral list, and to point out aspects of care peculiar to specific intoxicants.

Analgesics

Salicylate intoxication

A large number of salicylate preparations are available to the community, many of which do not mention the name "aspirin". Oil of wintergreen is methyl salicylate and is highly toxic.

Pharmacology. In normal therapeutic doses, acetyl salicylic acid is de-acetylated by plasma esterases and eliminated by conjugation. The volume of distribution is normally low but, when metabolic acidosis develops, tissue penetration increases.

In salicylate intoxication, prolongation of elimination occurs, the conjugation pathway rapidly becomes saturated and elimination is by the clearance of free salicylate via the kidneys. Salicylate clearance is pH-dependent, increasing 10-fold from a serum pH of 6 to that of 7.5.

Salicylates have a contradictory effect on acid–base balance. CNS stimulation of the respiratory centre may lead to respiratory alkalosis, whereas salicylate itself results in the accumulation of organic acid metabolites. The interaction between these two elements is variable and can be assessed only by frequent measurement of blood-gas tensions and acid–base state. Other important metabolic effects are hypo- or hyperglycaemia, and hypokalaemia from compensatory renal excretion.

There is increased risk of permeability-related oedema, although left ventricular failure may also occur secondary to cardiac arrhythmias, hypokalaemia or fluid overload. Clotting defects may

TABLE I. *Summary of management of salicylate poisoning*

Mild intoxication
  Observe fluid balance.
  Forced diuresis with large fluid turnover (4 litre/24 h).
  Repeat salicylate concentration measurement 2 h later to check that concentration is decreasing.
Moderate–severe intoxication
  Admit to ITU regardless of the level of consciousness.
  Administer activated charcoal orally or via a nasogastric tube: 5 g 4-hourly for six doses.
  Observe airway, ventilatory frequency, mental state and core temperature.
  Insert central venous pressure cannula.
  Measure acid–base balance 2-hourly.
  Forced alkaline diuresis.
  Maintain careful fluid balance charts and observe for fluid overload, pulmonary oedema and pulmonary aspiration.
  Haemodialyse if:
  1. "Severe" concentration does not decrease after 2 h of therapy.
  2. "Moderate" concentration increases to the "severe" range after 2 h of therapy.
  3. Onset of acute renal failure or pulmonary oedema secondary to fluid overload, unresponsive to diuretic therapy.

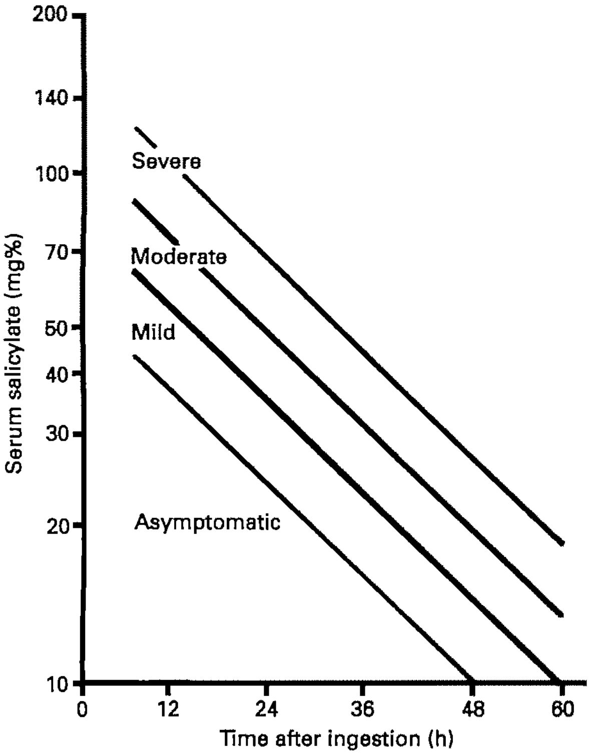

FIG. 1. Nomogram relating the serum salicylate concentration and expected severity of intoxication at varying intervals after ingestion of a single dose of salicylate (salicylate 13.8 mg = 1 mmol). (After Done, 1960 [6]; reproduced by permission of *Pediatrics*.)

occur because of inhibition of Factor VII production by salicylate.

Presentation. Restlessness, irritability and hallucinations; tinnitus; tachycardia; hyperventilation; pyrexia, sweating; occasionally, pulmonary oedema.

General management (table I). Gastric lavage if ingestion < 24 h. Activated charcoal in repeated doses via a nasagastric tube. Check salicylate concentration, blood-gas tensions, and concentrations of electrolyltes, clotting factors and blood glucose.

In severe intoxication (fig. 1), check also serum concentrations of proteins and calcium, and liver function tests. Hyperpyrexia is rare, but may require treatment.

Fluids and electrolytes. Ensure intravascular volume repletion with colloid, then give 1 litre of saline 1 mol litre^{-1} or 0.3 mol litre^{-1} every 4–6 h. Monitor urinary pH. If < 7.2, give 1 litre of saline 0.3 mol litre^{-1} with sodium bicarbonate 100 mmol i.v. over the subsequent 2 h, and review urinary pH. *Do not give more than 300 mmol of sodium per 24 h.*

Repeat measurement of the blood salicylate concentration after 2 h. If a "moderate" concentration has increased to the "severe" range, or there has been no decrease from the severe range, commence renal dialysis, or refer for renal dialysis. If there has been a decrease in the salicylate concentration, try to maintain the urinary pH > 7.2 with the use of sodium bicarbonate 50–100 mmol added to 1 litre of saline 0.3 mol litre^{-1}. Potassium chloride 60–120 mmol should be added to each 1 litre of i.v. solution.

Observe serum sodium, potassium and bicarbonate concentrations and pH.

Avoid fluid overload, metabolic alkalosis, hypernatraemia and hypokalaemia.

Should there be doubt about the fluid balance or the patient develops pulmonary oedema, pulmonary artery occlusion pressure monitoring is essential. A small pulmonary artery occlusion pressure should be aimed for.

Paracetamol intoxication

Pharmacology. Paracetamol is converted initially in hepatocytes to the potentially toxic metabolite n-acetyl-p-benzoquinoneimine (NABQI), which is conjugated rapidly to glutathione within the cell. In paracetamol overdose, glutathione stores are overwhelmed and unconjugated NABQI binds to proteins within the cell, producing necrosis. Increased concentration of intracellular calcium appears to play a fundamental role in the induction of cellular injury.

Paracetamol-induced liver damage is likely to be worse in patients taking hepatic enzyme-inducing agents, such as barbiturates or alcohol.

Paracetamol intoxication may also be complicated by renal failure and myocardial necrosis.

Presentation. Early (< 24 h): nausea and vomiting; confusion (occasionally); signs may be masked by additional drug ingestion. Late (> 24 h): severe vomiting; jaundice; evidence of acute hepatic failure, including encephalopathy, bruising and hypoglycaemia.

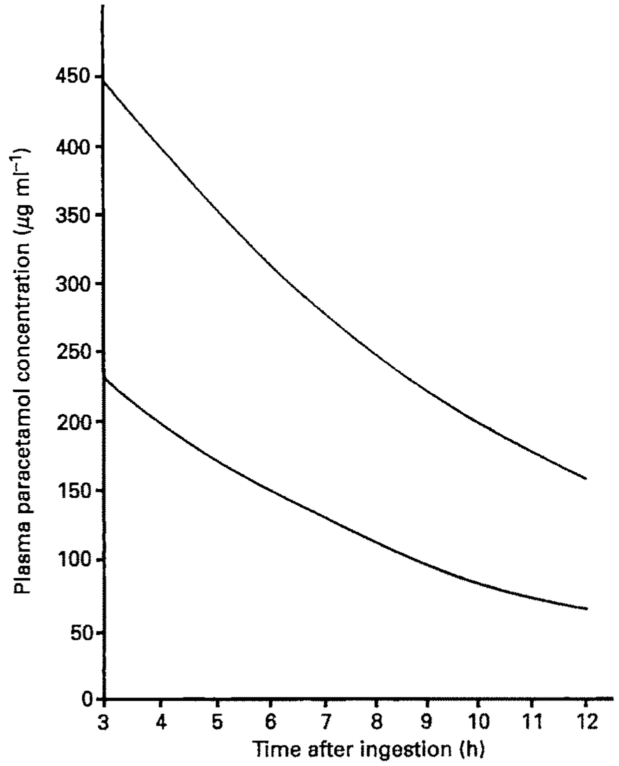

FIG. 2. Plasma paracetamol concentrations in relationship to time after overdose. Liver damage is likely to be severe above the upper line, mild to severe between the lines, and clinically insignificant under the line. (From Prescott and colleagues 1976 [30]; reproduced by permission of L. F. Prescott.)

Any patient with suspected intoxication MUST have a toxicological screen for paracetamol.

Management: gastric lavage within 4 h of ingestion, and antidote therapy.

There is now evidence to support the treatment of all patients with paracetamol intoxication with an antidote, regardless of the time of presentation, even if treatment is initiated when the patient has established fulminant hepatic failure [14].

The antidote should be used in patients who present at less than 8 h if more than 7 g of paracetamol has been ingested, or if the plasma concentration of paracetamol is above the lower line on the plot of paracetamol concentrations in relationship to time after overdose, shown in figure 2. Patients receiving enzyme-inducing agents should be treated at 70 % smaller concentrations.

At early presentation (within 8 h of ingestion), methionine may be given (2.5 g immediately, followed by three further doses 4-hourly). Patients presenting more than 8 h after ingestion of paracetamol should have their plasma paracetamol concentration assayed immediately. Antidote should then be given without delay and the paracetamol concentration checked again 4 h later. Failure of the plasma paracetamol concentration to decrease by 50 % may signify impending liver damage.

The antidote regimen should comprise acetylcysteine i.v. 150 mg/kg body weight in 5 % glucose 200 ml over 15 min, followed by 50 mg/kg body weight in 5 % glucose 500 ml over 4 h, followed by 100 mg/kg body weight in 5 % glucose 1000 ml over 16 h.

Occasionally, a histamine-mediated reaction develops in response to acetylcysteine.

Other aspects of management. Check clotting factors, electrolyte concentrations and liver function tests. Monitor capillary blood glucose concentration hourly. Monitor the patient's level of consciousness. Give glucose by i.v. infusion, to a total of 300 g daily. Observe for onset of renal failure. Renal dialysis may be necessary.

If ingestion was more than 24 h before presentation, and intoxication is assumed to be moderate to severe, observe for evidence of hepatocellular failure (deteriorating level of consciousness; increasing prothrombin time; pH less than 7.3) and introduce routine therapy for liver failure (these patients should be treated in an intensive therapy unit).

Referral to a centre particularly interested in the management of patients with paracetamol intoxication should be considered under the following circumstances [15]:

pH < 7.3 more than 24 h after ingestion
Prothrombin time > 45 s at 48 h
> 50 s at 72 h
Increasing serum creatinine concentration
Rapid development of grade 2 encephalopathy

Liver transplantation may be considered under the following circumstances [15]:

pH < 7.3
Prothrombin time > 100 s
Serum creatinine concentration > 300 μmol litre^{-1}
Coma grade 3 or 4
Increasing prothrombin time from day 3 to day 4 after overdose.

Cocaine intoxication

Pharmacology. Cocaine (benzoylmethylecognine) is absorbed from all mucosal surfaces and is most commonly taken i.v., by insufflation (intranasal) and by smoking (pulmonary). When it is insufflated, the peak action occurs at 30 min and lasts 60 min. The pharmacokinetic properties of i.v. cocaine are similar to those of smoked or inhaled cocaine.

"Crack" is the poorly water-soluble alkaloid form of cocaine, and is smoked. The onset of action is within minutes, and is dissipated within 20 min.

If ingested with alcohol, cocaine may be metabolized in the liver to a longer lasting more lethal metabolite [31].

Presentation. Clinical effects are the result of both peripheral and central nervous system stimulation. CNS stimulation: Euphoria, agitation, confusion; seizures; hyperthermia.

Peripheral vasomotor stimulation by noradrenaline results in tachycardia and hypertension.

Complications. Transient ischaemic attacks; cerebral haemorrhage; cardiac arrhythmias; hyperthermia leading to disseminated intravascular coagulation, cerebral oedema and rhabdomyolysis with acute renal failure; acute psychosis—paranoia, hallucinations and aggressive behaviour.

Differential diagnosis is from other conditions causing hypoxia, seizures, or both. The clinical picture may mimic neuroleptic malignant syndrome or acute withdrawal from sedative or hypnotic drugs

TABLE II. *Summary of pharmacology of antidepressant drugs*

Drug	Comment
Tricyclics	
Amitriptylene	Anticholinergic
Imipramine	Alpha-adrenergic agonist Life-threatening cardiotoxicity
Lofepramine	Cardiotoxic in mild overdose
Tetracyclic	
Mianserine	No anticholinergic effects Less cardiotoxic than tricyclics Drowsiness is main feature
Triazolopyridine derivative	
Trazadone	Unrelated to tricyclics Toxicity is mild—drowsiness, dizziness, occasionally coma
Aralkylketone	
Fluvoxamine	Serotonin uptake inhibitor Less serious toxicity
Trifluoro-oxypropylamine derivative	
Fluoxetine	Plasma half-life 2–3 days Major metabolite has plasma half-life 7–9 days Wide margin of safety Toxicity—CNS agitation, convulsions, nausea and vomiting
Dibenzoxapines	
Amoxapine, loxapine	Block dopamine receptors Mild cardiotoxicity High incidence of convulsions Rhabdomyolysis and acute renal failure may occur Management: Aggressive anticonvulsant therapy, early intubation. Diazepam ineffective in controlling seizures

or ethanol. Other drugs which may result in a similar presentation include the hallucinogens and anticholinergics.

General management. It is essential to exclude medical causes for agitation—for example hypoxia from pneumonia, meningitis or septicaemia.

The most important aspect of care is to control the psychomotor agitation and hence to prevent complications. Place in a single room where close monitoring is possible, but where intrusion is minimal.

Check oxygen saturation, ECG, core temperature and capillary blood glucose. Commence i.v. fluids and ensure intravascular volume repletion. Give Parentrovite ampoules 1 and 2 i.v. Cool by surface cooling if core temperature > 40 °C.

Indications for tracheal intubation and artificial ventilation: uncontrollable hyperthermia; extreme agitation with danger of aspiration; uncontrollable convulsions; deep coma with danger of aspiration.

Sedation. Sedate with diazepam i.v. until agitation and seizures stop. If the required dose causes respiratory depression, tracheal intubation and artificial ventilation may be necessary. Continue regular doses of diazepam—for example 10 mg 4–6 hourly.

Other medications. Do not use neuroleptic agents. Beta-adrenergic antagonists should be avoided unless the patient is heavily sedated, because this may lead to increased alpha-adrenergic activity and increasing hypertension.

Management of cardiac arrhythmias and hypertension. Supraventricular tachycardias are common and are often caused by hyperthermia and agitation, requiring no specific antiarrhythmic therapy.

Ventricular tachyarrhythmias should be treated appropriately, the patient sedated and the lungs ventilated artificially. Lignocaine may be considered as a temporary measure, and alpha–beta-block (labetalol) or beta-block (atenolol or propranolol) may be used when the patient is undergoing artificial ventilation.

Severe hypertension which has failed to respond to sedation and artificial ventilation should be treated with vasodilators such as labetalol, or sodium nitroprusside by i.v. infusion.

Treatment of rhabdomyolysis. Rhabdomyolysis is generally associated with severe muscle pain and contractures, and is frequently complicated by acute renal failure (ARF) which may require dialysis. The management of acute rhabdomyolysis has been discussed earlier in this review.

Additional investigations. Check concentrations of serum creatine phosphokinase and urine myoglobin; perform blood and urine drug screen (including alcohol); a computed tomography scan is advisable in order to exclude complicating intercerebral pathology; blood and urine cultures.

Amphetamines and MDMA (Ecstacy)

Amphetamines may be injected, inhaled or taken orally.

Pharmacology: Methyl amphetamine (ice) is available as crystals and is smoked. It is 20 times as potent as amphetamine sulphate, with effects which are similar. 3,4-Methylene dioxymethamphetamine (MDMA) has fewer side effects in the usual dose of 200 mg taken orally, but sudden death from ventricular fibrillation has been reported.

Presentation is similar to that following intoxication with cocaine.

Management. Similar to management of cocaine intoxication. Clearance of amphetamine is increased by urinary acidification, but this should be avoided in the presence of rhabdomyolysis.

Heroin (diamorphine)

Heroin deaths are caused generally by respiratory depression with or without pulmonary aspiration. This may occur with first use, change in drug access (variability in purity) or loss of tolerance after a period of abstinence.

Presentation: coma, with slow ventilatory frequency (terminating in apnoea); pinpoint pupils (not present in pethidine intoxication).

Diagnosis. Classically, a temporary reversal of coma and respiratory depression is achieved with naloxone 0.8–2 mg i.v. Antagonism may require larger doses of naloxone if the intoxication is caused by pethidine, buprenorphine, or dextropropoxyphene, and may be suppressed by the presence of other drugs.

Treatment. Some authors suggest the use of i.v. naloxone to maintain antagonism. In our opinion, this requires very careful titration, and we consider it safer to intubate the trachea and ventilate the lungs until the intoxicant effect has worn off spontaneously.

Complications include pulmonary aspiration, noncardiogenic pulmonary oedema, rhabdomyolysis and infective complications in i.v. drug abusers.

Drug couriers. "Body packers" as they are termed, smuggle drugs by concealment in and around the body. Should the drug be swallowed in a container (e.g. condom, plastic bag or vial), leakage may lead to severe toxicity. A recent plane journey may be an indication for an abdominal x-ray. Surgical removal from the bowel may be indicated.

Psychoactive Drugs

Pharmacology. The antidepressant agents have differing activities, summarized in table II.

Tricyclic intoxication

Presentation. Cardiovascular and neurological features dominate the clinical picture.

Cardiac: hypotension; cardiac arrhythmias (ventricular and atrial); ECG abnormalities (PR, QRS and QTc prolongation). A right bundle branch block pattern is characteristic [3]. With QRS > 0.1 s, convulsions are likely; QRS > 0.16 s, ventricular arrhythmias are likely. Terminally, refractory hypotension may occur, leading to electromechanical dissociation (EMD).

CNS: convulsions; agitation, hallucinations; coma and respiratory depression.

General management. In any patient with evidence of a cardiac arrhythmia, twitching or respiratory depression, the trachea should be intubated and the lungs ventilated. Therefore, in the majority of severe intoxications, even if the patient is still conscious, he/she should undergo elective ventilation.

This management is recommended because respiratory depression, hypercapnia and hypoxia often precipitate cardiac arrhythmias; acidosis, whether respiratory or metabolic, enhances cardiotoxicity; and intubation of the trachea and ventilation of the lungs ensure preservation of the airway and safe use of anticonvulsants (e.g. benzodiazepines) which are less negatively inotropic than phenytoin.

Management of myocardial depression and arrhythmias. With good oxygenation and maintenance of pH > 7.4, cardiac arrhythmias usually resolve. Small incremental doses of sodium bicarbonate 50 mmol should be used to maintain pH > 7.4 if hyperventilation fails to achieve that goal. EMD may be precipitated by the administration of negatively inotropic agents; these should be avoided unless the arrhythmia is so bizarre that the cardiac output is not being maintained. Sodium bicarbonate 50 mmol i.v. may be effective, but if this fails, small incremental doses of lignocaine are probably the safest treatment.

Inotropes may be required, and dobutamine is suitable. Invasive haemodynamic monitoring with a pulmonary artery catheter is tempting, but should be avoided because insertion of the catheter during the acute early phase may precipitate a dangerous arrhythmia. Whilst d.c. shock may be used, it may precipitate asystole or EMD. The joule dosage should be kept to a minimum.

Physostigmine is *not* recommended.

Cardiac toxicity generally resolves within 6 h, and artificial ventilation for control of convulsions is rarely indicated after 24 h.

Monoamine Oxidase Inhibitors

Pharmacology. Overdose of these drugs alone does not produce any serious effects. Severe toxicity may occur when they are taken together with foodstuffs or drugs contraindicated during their use (e.g. foods containing precursors of biogenic amines such as tyramine, or drugs such as tyramine, sympathomimetic amines or amphetamine).

Presentation. Symptoms develop progressively over 12–24 h and include: muscle twitching, leading to diffuse muscle spasm, trismus and opisthotonos; fluctuations in arterial pressure with tachycardia; fixed, dilated pupils; hot sweaty peripheries and increased core temperature.

Complications include rhabdomyolysis, acute renal failure and disseminated intravascular coagulopathy.

Management. Control of core temperature > 39 °C by sedation, paralysis and cooling. Control of haemodynamic state, with invasive monitoring as required.

Antipsychotic Drugs

Pharmacology. These are the phenothiazine derivatives and may be grouped according to their dominant effects:

Group 1 (e.g. chlorpromazine): characterized by pronounced sedative effects and moderate anticholinergic and extrapyramidal effects.

Group 2 (e.g. thioridazine): characterized by moderate sedative effects, marked anticholinergic effects and fewer extrapyramidal effects than groups 1 or 3.

Group 3 (e.g. perphenazine): characterized by fewer sedative effects and anticholinergic effects, but more pronounced extrapyramidal effects than groups 1 and 2.

Presentation. Clinical features may include: respiratory depression; cardiac arrhythmias (the ECG may show a prolonged QT interval); sudden death (probably as a result of torsades de pointes); dystonia (generally relieved by procyclidine 5–10 mg i.v.); coma and convulsions; hypothermia; neuroleptic malignant syndrome (confusion, muscle pain and rigidity, rhabdomyolysis, fever).

General management: supportive care; maintain pH > 7.4; ensure a normal serum potassium concentration.

Management of torsades de pointes: d.c. shock and cardiac pacing 20 beat min^{-1} greater than the patient's sinus rhythm; infusion of isoprenaline 2–6 µg min^{-1} may be tried whilst pacing is established.

Sedative and Hypnotic Agents

Benzodiazepine overdosage

Death is caused by respiratory depression and aspiration of vomitus, but note that these drugs are often taken in combination with other drugs, resulting in a confusing clinical picture.

In our opinion, flumazenil should not be used for treatment because it may precipitate convulsions or acute withdrawal syndromes, and it has a short half-life (1–2 h), making repetitive doses and continued monitoring necessary.

Management: supportive care with intubation and ventilation if required.

Carbon monoxide poisoning

In England and Wales, approximately 1000 people die every year from carbon monoxide poisoning. Most of these patients do not reach hospital. Common sources of carbon monoxide are car exhaust fumes, improperly maintained and ventilated heating systems, smoke from fires, and household gas.

Pharmacology. Carbon monoxide has an affinity for haemoglobin which is 200–250 times that of oxygen. Carbon monoxide combines with haemoglobin to form carboxyhaemoglobin, and the affinity for oxygen of the remaining haem is increased. Carbon monoxide toxicity is caused by cellular anoxia, and possibly also inhibition of cellular respiration as a result of binding to other haem proteins. The elimination half-life of carbon monoxide is reduced from 250 min when the subject is breathing air, to 59 min breathing 100% oxygen, and is reduced further to 22 min when 100% oxygen is breathed at 2.2 atm.

The severity of poisoning depends on the concentration of carbon monoxide in the air, the duration of exposure and the person's general health.

Presentation. Repeated exposure: headache; fatigue; poor memory and concentration; dizziness and paraesthesia; visual disturbances; chest pain; diarrhoea and abdominal pain.

Acute exposure: carboxyhaemoglobin $< 10\%$—generally no symptoms; carboxyhaemoglobin $> 60\%$—coma, leading to cardiorespiratory arrest.

Late sequelae may include neuropsychiatric sequelae which may develop weeks after exposure (memory loss, impaired intellect, signs of cerebellar and mid-brain damage).

Signs of poisoning include: cherry red skin, coma, hyper-reflexia, convulsions and cardiac arrhythmias.

General management. Remove from site; administer 100% oxygen via tight fitting face mask (where there is respiratory depression or difficulty with airway control, intubate the trachea and ventilate the lungs with 100% oxygen); in cases of severe poisoning, assume cerebral oedema and treat accordingly.

Indications for hyperbaric oxygen therapy include: a conscious patient with a carboxyhaemoglobin $> 20\%$; depressed level of consciousness, but able to maintain airway; recovery of consciousness after an initial carboxyhaemoglobin $> 40\%$.

Contraindications to hyperbaric oxygen therapy via a single person chamber include: artificial ventilation; inability to maintain an airway; hypovolaemia or dependence on cardiac inotropes; cardiac arrhythmias potentially requiring urgent intervention; asthma.

These contraindications arise because of the practical difficulties of managing such patients in single person hyperbaric oxygen chambers, and the limited availability of compressed air chambers in which medical attendants can also be pressurized. All patients fulfilling the indications for hyperbaric oxygen therapy should be discussed with the regional hyperbaric oxygen facility. (The availability of hyperbaric oxygen facilities may be ascertained by contacting the Diving Diseases Research Centre, who provide a 24-h service. Tel.: 0752-261-910.)

Lithium intoxication

Pharmacology. This metal is eliminated by the kidney, therefore renal failure may lead to accumulation. Other circumstances which may lead to toxicity when lithium is being used for treatment include dehydration and concomitant administration of non-steroidal anti-inflammatory agents or diuretics.

Presentation. Neurological: confusion, agitation; hyper-reflexia, hypertonia, tremor; ataxia; convulsions.

Gastrointestinal: vomiting.

Metabolic: hyponatraemia; diabetes insipidus; renal failure.

The therapeutic range in blood is lithium 1.0–1.4 mmol litre^{-1}. In acute poisoning the lithium concentration is generally > 5.0 mmol litre^{-1}.

General management: gastric lavage up to 4 h after ingestion; forced diuresis. In the presence of neurological symptoms, renal failure, or both, haemodialysis should be performed.

SHORT COMMUNICATIONS

EFFECT OF AGE ON THE SENSITIVITY OF UPPER AIRWAY REFLEXES

R. J. ERSKINE, P. J. MURPHY, J. A. LANGTON AND G. SMITH

SUMMARY

We have recorded the threshold concentration of inhaled ammonia vapour required to elicit reflex glottic closure (NH_3TR) in 102 healthy, non-smoking volunteers (39 female) aged 17–96 yr in order to assess the effect of age upon upper airway reflex sensitivity. A single measurement of sensitivity was made in each subject using a system delivering small concentrations of ammonia vapour for single intermittent breaths to the upper airway and recording glottic closure using an inspiratory pneumotachograph. We found a strong positive correlation between age and NH_3TR, indicating a decrease in upper airway reflex sensitivity with increasing age. (Br. J. Anaesth. 1993; **70**: 574–575)

KEY WORDS

Age factors. Airway: reflex sensitivity.

Reflex activity is thought to diminish with advancing age. Laryngeal reflexes in the elderly appear to be less active, both during induction of anaesthesia and in the recovery room, compared with the younger patient—suggesting that protection of the airway may be impaired in the elderly [1].

The protective reflex of the larynx is evoked by stimulation of receptors thought to be located in the hypopharynx and larynx. With concentrations of irritant vapour smaller than that required to produce cough, the response is glottic closure, and a brief pause in inspiration. The upper airway is sensitive to both chemical and mechanical stimuli, the former being both quantifiable and reproducible [2].

Using equipment described previously [2], we have measured the threshold concentration of ammonia vapour (NH_3TR) required to stimulate reflex glottic closure in patients. Previous workers [3] found a six-fold increase in the concentration of inhaled ammonia vapour required to produce a reflex stop in inspiration in patients between the second and eighth and ninth decades. However, that study population contained a large proportion of smokers and our early work [4] has shown that smokers have considerably more sensitive upper airway reflexes than non-smokers.

The aim of this study was to measure NH_3TR in non-smokers over a broad age range in order to assess the effect of age alone on upper airway reflex sensitivity.

METHODS AND RESULTS

After obtaining Ethics Committee approval and informed subject consent, we studied 102 healthy, non-smoking subjects aged 17–96 yr. The majority (85) were preoperative elective surgical patients, the remainder being members of our department, nursing staff and nine patients from geriatric wards. We excluded those with mental or neurological impairment, chronic bronchitis and asthma, a history of upper respiratory tract infection in the past month, and those receiving sedative medication. Two subjects had smoked in the past: one stopped 25 yr previously, the other stopped 4 weeks before the study.

Measurements were made either in our laboratory or on the ward, using the same portable equipment. A single measurement of NH_3TR was made in each subject, using the method described previously [2]. We have found that no significant difference exists between repeated measures made on the same day and on separate days in the same individual [2].

NH_3TR was plotted against age for each subject (fig. 1); there was an increase in NH_3TR with advancing age. The correlation coefficient was calculated as +0.85, indicating a strong positive correlation between age and NH_3TR.

Mean NH_3TR for the age group 21–30 yr ($n = 14$) was 571 (SEM 41.5) p.p.m., compared with a value of 1791 (52) p.p.m. for the group aged 86–95 yr ($n = 14$).

COMMENT

Whilst loss of peripheral reflexes in the elderly may be of little anaesthetic significance, the reduction in the sensitivity of upper airway reflexes associated with age may be important, particularly after anaesthesia or sedation, when full airway protection may be delayed, with a consequent increased risk of aspiration [1].

In 1960, Pontoppidan and Beecher carried out a similar study using ammonia vapour [3]. They

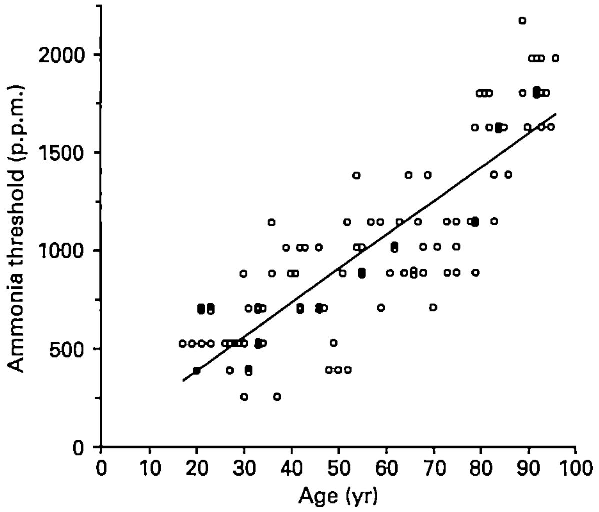

FIG. 1. Correlation between age and ammonia threshold. Regression equation: $y = 17.1x + 43.4$; correlation coefficient: $+0.85$.

assessed 103 subjects aged 15–84 yr and found that the threshold increased more than six-fold from the second to the eighth and ninth decades, and that the between-subject variability in sensitivity increased with age. However, we have identified several factors that may have produced inaccuracies.

First, their breathing system contained a large canister into which the ammonia vapour was injected. This could have allowed streaming to occur and, depending upon inspiratory flow and the timing of inspiration, could have produced a variable concentration of ammonia. Also, depending upon the tidal volume and inspiratory flow rate of the subject, the stimulus may have been presented to the upper airway at differing times during the ventilatory cycle. The authors stated that the actual concentration of inhaled ammonia was unknown, but was assumed to be directly proportional to the absolute amount of ammonia used. Furthermore, seven subjects failed to respond to the maximum delivered stimulus of ammonia. Second, they used a metabolic spirometer to record the change in inspiratory flow, and not a pneumotachograph. Finally, their population contained a high proportion of smokers (85 %), although this varied between 33 % in the 70–79 yr group and 83 % in the 50–59 yr group, but they could find no consistent influence of smoking upon airway irritability. In contrast, we have found that those subjects who regularly smoke more than 15 cigarettes per day have a significantly smaller NH_3TR than non-smokers of the same age [4], indicating that smokers have more sensitive upper airway reflexes. Therefore, in this study we have excluded smokers.

In essence, our results support Pontoppidan and Beecher's work, indicating an increase in NH_3TR with increasing age, but we found the mean NH_3TR increased only three-fold from the third to the ninth and tenth decades—a change which was only 50 % of that of their study. In addition, we found no increase in between subject variability in NH_3TR with age and, in general, our results were more tightly clustered in each age group. These differences between the earlier study and ours, in particular regarding distinction between smokers and non-smokers, may be explained by the improved design of our system, which delivers a more constant, known concentration of ammonia vapour [2].

The cause of this increased threshold in the elderly is unknown. The irritant receptors in the upper airway are thought to consist of free nerve endings ramifying among epithelial cells; they have been classified as type 1, rapidly adapting receptors, although no nervous end-organ has been identified histologically. Increasing age is associated with a reduction in the population of nerve endings and this, combined with the thickening that occurs in the mucosa of the upper airway thus reducing penetration of noxious chemicals, may lead to an increase in stimulation threshold. A decrease in amplitude of electrical potentials in pulmonary afferent vagal fibres with age (possibly caused by degenerative changes in sensory neurones of the Nodose (Vagal) ganglion) has been described in humans [5]. A similar mechanism may affect fibres from the superior laryngeal nerve. A histological study of age-related changes in the rat superior laryngeal nerve has demonstrated segmental demyelination and axonal degeneration in the elderly group and other ultrastructural changes associated with complete fibre dysfunction [6]. Several of these changes resemble those seen in aged human peripheral nerves, in which a decrease in fibre numbers is also a significant feature [5].

It is not possible to infer directly from our results that a progressively greater NH_3TR associated with advancing age implies a loss of protective reflexes and consequent increased risk of aspiration. However, the increased reflex stimulus threshold in the elderly may be a contributory factor, and emphasizes the need for increased vigilance during recovery from anaesthesia or sedation.

ACKNOWLEDGEMENTS

This study was supported by a grant from the Trent Regional Health Authority and an equipment grant from The Association of Anaesthetists of Great Britain and Ireland.

ENDOBRONCHIAL CUFF PRESSURES

M. COBLEY, J. F. KIDD, B. A. WILLIS AND R. S. VAUGHAN

SUMMARY

In 20 adult patients (18 male) who presented for thoracotomy, the trachea was intubated using Mallinckrodt disposable double-lumen tubes (18 large and two medium). The endobronchial cuff was inflated by a trained operating department assistant using an air-filled syringe. The volume of air and the initial endobronchial cuff pressure were measured. The minimum cuff pressure required to prevent respiratory gas leakage from the isolated lung was measured also and maintained using the Cardiff Cuff Controller. Mean initial cuff pressure was 69.3 (SEM 6.0) mm Hg, whereas the mean minimum cuff pressure was 29.5 (4.0) mm Hg (P < 0.0001). The results suggest that the method described of inflating the endobronchial cuff may lead to overinflation and subsequent excessive pressure on the endobronchial wall. (Br. J. Anaesth. 1993; **70**: 576–578)

KEY WORDS

Equipment: double lumen tubes, endobronchial cuff pressures.

The inflatable cuff of the endobronchial limb of the double-lumen tube has two functions. It allows independent positive pressure ventilation of the one lung and also selectively isolates the other lung. It is recognized that excessive cuff pressure exerted on the tracheal wall is associated with trauma [1]. To minimize these problems, high volume low pressure cuffs and an electropneumatic instrument for measuring and controlling cuff pressures have been devised [2].

Tracheal rupture may be produced by tracheal tubes. Incidents of bronchial rupture have also been reported, but are rarer and have been associated with the use of the older and stiffer high pressure cuffs of the Robertshaw [3] and Carlens [4] types.

Rapid inflation of the endobronchial cuff is thought to be the cause of bronchial rupture [3, 4]. Measurement of tracheal cuff pressure is performed rarely in clinical practice, but an earlier study by Willis, Latto and Dyson [5] showed that such measurements can prevent accidental overinflation of the tracheal cuff. Furthermore, the use of the Cardiff Cuff Controller allows the clinician to maintain the cuff at a predetermined pressure—ideally, the minimum necessary to prevent leakage. It seems reasonable to suppose that the endobronchial cuff is also susceptible to accidental overinflation.

The aim of this study was two-fold: first to measure the initial endobronchial cuff pressure (ECPi) produced by syringe inflation, performed under normal clinical conditions by a trained operating department assistant; second to measure the pressure, in the same endobronchial cuff, which just prevented leakage of gas from the isolated lung, but using the Cardiff Cuff Controller rather than syringe inflation. This pressure was deemed the minimum endobronchial cuff pressure (ECPmin).

METHOD AND RESULTS

Two instruments were used to measure pressure. The first measured ECPi and was a portable, electrically powered pressure transducer with a built-in amplifier and digital display. The transducer possessed a low compliance with a small internal volume (150 µl) which allowed measurement of the pressure within an inflated cuff by connecting the cuff pilot balloon directly to the transducer. The transducer response was linear over the range 0–200 mm Hg, and a built-in reference voltage permitted calibration.

The Cardiff Cuff Controller was used to measure and maintain ECPmin. This instrument is an electropneumatic device which incorporates the same pressure transducer for measurement, but has the additional facility to maintain a constant cuff pressure at a preset value in the range 5–150 mm Hg, to within 1 mm Hg.

We studied 20 patients (18 male) undergoing elective thoracotomy. Their mean age, height and weight were 56.3 (SEM 2.5) yr, 169 (SEM 1.7) cm and 69.3 (SEM 2.4) kg, respectively. After induction of anaesthesia and neuromuscular block, the lungs were ventilated with 66 % nitrous oxide and 1 % enflurane

Correspondence to M. C.

in oxygen. A right- or left-sided, double-lumen, disposable, Mallinckrodt endobronchial tube with high volume and low pressure cuffs was inserted and positioned accordingly. These tubes are manufactured in three sizes, large, medium or small. The large size was used for all male patients (18) and a medium size for females (two). Seventeen tubes were left-sided and three right-sided; all the right sided tubes were placed in male patients.

A three-way tap was connected to the pilot balloon of the endobronchial cuff and the cuff was inflated carefully by a trained operating department assistant using a 5-ml, air-filled syringe via this tap. The air was injected in small increments of 0.5 ml until no discernible leak was detected by the anaesthetist. Assessment of the presence of leak past the endobronchial cuff, at a standardized inflation pressure of 25 cm H_2O, was achieved by auscultation of both sides of the chest during one-lung ventilation, with only the bronchial cuff inflated. The lung port of the non-dependent, unventilated lung was open to atmosphere and helped to determine any leak past the bronchial cuff by noting the presence or absence of expired gases. If, during the incremental injection of air, resistance to injection was felt, the final 0.5-ml increment was decreased carefully until no leak was detectable as assessed by our method. The final volume of air injected was noted. The three-way tap was connected to the pressure transducer and ECPi measured.

The investigators consider this method of endobronchial cuff inflation to be the technique practised most commonly. Although great care is exercised not to over inflate the cuff, we suspect that the obvious lack of sensitivity of this method may inadvertently produce overinflation of the endobronchial cuff.

Subsequently, the three-way tap was attached to the Cardiff Cuff Controller and the pressure in the cuff (ECPi) was modified precisely until the cuff pressure was just sufficient to prevent gas leakage from the isolated lung as detected by auscultation, in the same manner as described earlier and at the same inflation pressure. At this point, the new cuff pressure (ECPmin) was noted. The cuff was maintained at this preset pressure for the duration of the operation. Any leak that occurred during the procedure was noted and the new cuff pressure necessary to prevent leakage was recorded. This pressure was maintained for the remainder of the operation. The mean duration of operation was 3 (SEM 0.1) h.

In addition, *in vitro* endobronchial cuff pressure *vs* volume curves were plotted for the double-lumen tubes used.

The mean pressures and the volumes of air injected into the cuff to achieve the mean ECPi and the mean ECPmin are shown in table I. The overall mean ECPi was 69.3 (SEM 6.0) mm Hg, with a mean ECPi for right-sided tubes of 65.7 mm Hg and mean ECPi for left-sided tubes of 69.9 mm Hg. This compared with an overall mean ECPmin of 29.5 (SEM 4.0) mm Hg: right-sided tube mean ECPmin 24.6 mm Hg and left-sided mean ECPmin 30.32 mm Hg. Using a paired Student's t test, a significant difference was demonstrated between mean ECPi and ECPmin ($P < 0.0001$).

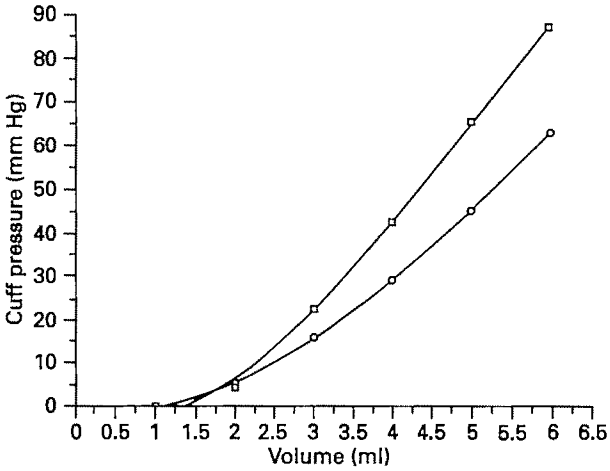

FIG. 1. Endobronchial cuff pressure produced by inflating medium (○) and large (□) double-lumen tubes with various volumes of air.

When they were inflated *in vitro* with 4 ml of air (maximum *in vivo* inflation volume) the bronchial cuff of both the large and medium size tubes had a diameter of 2.3 cm and they developed cuff pressures of 65 mm Hg and 44 mm Hg, respectively. Inflation with 2.5 ml of air (mean *in vivo* volume) produced a cuff diameter of 2.0 cm and cuff pressures of 13 mm Hg and 10 mm Hg, respectively (fig. 1). These diameters compare with the actual bronchi sizes of right bronchus (male 1.2–2.1 cm (mean 1.7 cm); female 1.1–2.0 cm (mean 1.5 cm)) and left bronchus (male 1.0–1.8 cm (mean 1.5 cm); female 0.9–1.5 cm (mean 1.2 cm)). Thus the greater cuff pressures *in vivo* are caused by pressure exerted against the bronchus.

COMMENT

The difference between manual syringe inflation of the cuff and the electropneumatic method lies in the relative lack of sensitivity of the former method. Small changes in the volume injected into the cuff result in relatively large increases in cuff pressure. The Cardiff Cuff Controller controls pressures to within 1 mm Hg and, although the end-point is the same (absence of auscultated leakage passed the cuff), the manual inflation method usually overshoots that end-point pressure. Therefore, syringe inflation, however carefully performed, clearly produces overinflation of the endobronchial cuff and this can exert an unnecessarily great pressure on the bronchial mucosa.

In the absence of an auscultated leak, aspiration is an unlikely event. However, an overinflated cuff may result in ischaemic damage to the mucosa with subsequent stenosis or, in cases of gross overinflation, bronchial rupture. The optimum pressure for a cuff is the pressure which prevents aspiration, allows leak-free ventilation and does not produce bronchial mucosal ischaemia. As the incidence of bronchial mucosal damage is not known, it is safer to maintain the bronchial cuff at that pressure which justs prevents auscultated leakage.

The tracheal cuff pressure has been shown to equal the pressure exerted on the tracheal wall with high volume, low pressure cuffs. There seems no reason to suppose that the high volume, low pressure endobronchial cuff differs. Tracheal damage is attributed to both increased lateral wall pressure and the duration of anaesthesia, with lateral wall pressure the more important factor (6). Moreover, a linear increase in cuff pressure over a 3-h period has been demonstrated when the inspired gases contain nitrous oxide. These risk factors are no less relevant when considering endobronchial cuffs. The high lateral bronchial wall pressure which may develop with overinflated cuffs can impair mucosal blood flow and thereby contribute to the risk of bronchial rupture.

To reduce the risk of inadvertent overinflation, the anaesthetist should instruct the assistant to inflate the cuff just enough to abolish a leak from the isolated lung. The temptation to add additional volume for good measure should be strongly discouraged. We have shown that careful syringe inflation alone is not necessarily enough to prevent overinflation of the cuff. The use of a cuff pressure controller such as the Cardiff Cuff Controller [2], with its greater sensitivity of control, enables cuff pressure to be set more precisely and accurately to a specific value known just to eliminate leakage. The cuff pressure can also be maintained at the chosen pressure even in the presence of nitrous oxide when significant pressure increases resulting from diffusion of nitrous oxide into the cuff have been reported.

LIPID SOLUBILITY OF PANCURONIUM AND VECURONIUM DETERMINED BY N-OCTANOL/WATER PARTITIONING

M. WEINDLMAYR-GOETTEL, H. GILLY, E. SIPOS AND
K. STEINBERIETHNER

SUMMARY

We have measured the n-octanol/water distribution coefficients at 37 °C of two steroidal myoneural blockers (pancuronium and vecuronium) and of their 3-hydroxy metabolites over a pH range from 1.5 to 11. Pancuronium was found not to be lipid soluble. The mean distribution coefficient of 3-hydroxy vecuronium at pH = 7.4 was 0 and that of vecuronium 0.12 (SD 0.1). Distribution coefficients of the parent drug showed a slightly greater lipid solubility than the metabolite (11.37 (2.91) and 9.53 (3.44), respectively (mean $t_{0.05} \times$ SE)). Because of its lipid solubility, vecuronium may penetrate into lipid structures. (Br. J. Anaesth. 1993; **70**: 579–580)

KEY WORDS

Biotransformation: metabolites. Neuromuscular relaxants: pancuronium, vecuronium.

The lipid solubility of a drug is of utmost importance for its disposition within the body and, in particular, for its permeation through membranes [1]. The lipid solubility of a compound is expressed in terms of its distribution coefficient between a model lipid, mostly n-octanol, and an aqueous buffer solution [1, 2]. In general, the lipid solubility of drugs used in anaesthesia, such as opioids and analgesics, has been investigated thoroughly [2]. For myoneural blockers, however, to our knowledge no quantitative data are available.

METHODS AND RESULTS

The validity of our analytical approach was verified by determining the distribution coefficients (L) of compounds with well-known, high and low lipid solubility (salicylic acid: $L = 162$, p$K = 3.0$; sulphanilic acid: $L = 0.00013$, p$K = 3.2$ [1]). Optimum conditions for the determination of distribution coefficient were evaluated in preliminary experiments. Each pH-adjusted solvent (Davis buffer [3]) was presaturated with n-octanol. The n-octanol was equilibrated with the aliquot amount of pH-adjusted reference solutions containing salicylic acid and sulphanilic acid (at room temperature) or neuromuscular blockers (at 37 °C). An equilibration period of 2 h was found to be sufficient [2].

Concentrations of salicylic acid and sulphanilic acid in the water phase were measured photometrically, the myoneural blocker was quantified by HPLC [4]. Up to 12 samples were analysed at each pH value. The distribution coefficients were calculated according to the formula given by Le Petit [3].

Data are presented as means ($t_{0.05} \times$ SE). An non-sigmoid function as deduced by Le Petit [5] was used to approximate the pH dependence of the distribution coefficient using software package Fig. P (Version 6.0 c, Software Corporation, Durham North Carolina, U.S.A.). Statistical significance was checked using the t test, assuming the level of significance to be 95% ($P < 0.05$).

The mean distribution coefficient of salicylic acid measured at pH 1.5 was 161.2 (SD 3.1). The value resulting from the curve fitting of all measurements at 25 °C was 176.52 ($t_{0.05} \times$ SE 7.44), which corresponds to the nominal value ([1]-pH not specified). The n-octanol/water distribution coefficient of sulphanilic acid was less than the detection limit of 0.02 (pH 1.5–8).

Independent of pH, the distribution coefficient of pancuronium was less than the detection limit. Pancuronium remained stable in the aqueous solution at pH values less than 8. 3-Hydroxy pancuronium could be detected only at pH > 8.0; however, the concentration of this metabolite did not exceed 5%, even at pH 11.

n-Octanol/water distribution coefficients of vecuronium in the presence of its 3-hydroxy metabolite are presented in figure 1. The data fitting yielded a partition coefficient of 11.37 ($t_{0.05} \times$ SE 2.91). Vecuronium is stable only in highly acid solutions and, when dissolved in water, it decomposes into its metabolites. At pH 7.4, about 60% and at pH 11, almost 100% of vecuronium is de-acetylated into both 3-hydroxy vecuronium (up to 85%) and 3,17-dihydroxy vecuronium (up to 15%). For this reason, the data measured represent the solubility of vecuronium/3-hydroxy vecuronium and the 3,17-dihydroxy metabolite rather than that of pure vecuronium. In figure 1 also, the results of 3-

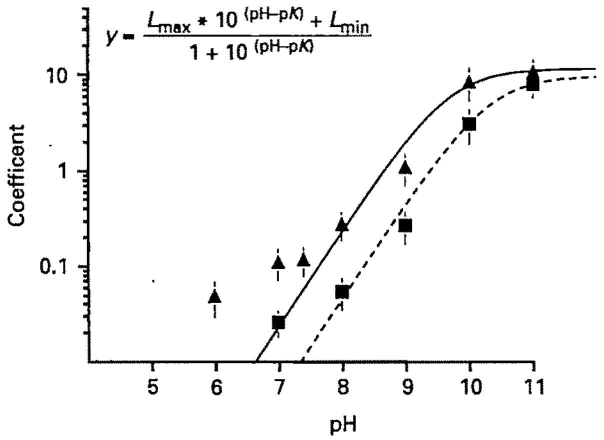

FIG. 1. Distribution coefficient (L) *vs* pH for mixture of vecuronium and its metabolite, 3-hydroxy vecuronium ($n = 95$) (▲) and for 3-hydroxy vecuronium ($n = 30$) (■) (mean ($t_{0.05} \times$ SE)). For curve fitting, all individual data were used. Resulting curve parameters were: vecuronium—$L_{max} = L_{pH\text{-}14} = 11.37$ (2.91); $L_{min} = L_{pH\text{-}0} = 0.0$ (1.10); p$K = 9.69$ (0.52). 3-Hydroxy vecuronium—$L_{max} = L_{pH\text{-}14} = 9.53$ (3.44); $L_{min} = L_{pH\text{-}0} = 0.0$ (1.07); p$K = 10.32$ (0.57).

hydroxy vecuronium are presented. At pH values greater than 7, the distribution coefficient increases, forming a characteristic curve.

COMMENT

In order to assess our analytical technique for determining lipid solubility, quality control was performed by using two reference substances, salicylic acid and sulphanilic acid. The values obtained for the n-octanol/water solubility of salicylic acid are in good agreement with the published data [1]. The distribution coefficient of sulphanilic acid—selected for its extremely low lipid solubility—is less than 0.02.

Until now, steroidal myoneural blockers as quaternary amines were considered to be insoluble in lipids [2]. It is surprising that no exact data of their distribution coefficients are given, which rules out comparison of the various myoneural blocking agents.

For all our tests we used pancuronium, vecuronium and the metabolites as pure substances (without stabilizing agents). However, when the stock solution was prepared by dissolving the pure substances in water, the pH-dependent chemical instability, especially of vecuronium, had to be taken into account. Therefore, the quantities of both the parent compound and the main metabolites were determined in each sample. We had to perform a separate test series with the object of determining the lipid solubility of this metabolite, also.

Vecuronium and 3-hydroxy vecuronium yielded similar distribution coefficients (11.36 (2.91) *vs* 9.53 (3.44)) and, as could be expected from theoretical considerations, the more polar deacetylated metabolite has a somewhat smaller distribution coefficient. Both substances appear to be lipid-soluble at pH > 8. Within the physiological pH range, however, the n-octanol/water distribution coefficient of vecuronium was significantly greater than the detection limit.

The distribution coefficient of pancuronium proved to be extremely small, hence it can be concluded that pancuronium is lipophobic. Even in the high pH range, the amount of 3-hydroxy pancuronium in the buffer solution was less than 5%; as a result its distribution coefficient was not measured.

In conclusion we state that, although the lipid solubility of vecuronium is low, it is markedly greater than that of pancuronium. When pH derangement occurs (e.g. alkalosis), penetration of vecuronium and its metabolites into lipid structures would therefore be more pronounced than that of pancuronium. Clinical consequences of this observation have not been investigated so far, but greater penetration of vecuronium than of pancuronium through the blood–brain barrier has been observed in animal experiments [6]. This may be significant in cerebral trauma or neurosurgical patients with impaired blood–brain barrier function.

TETANIC FADE DURING RECOVERY FROM VECURONIUM BLOCK: COMPARISON OF SYSTEMIC AND ISOLATED FOREARM ADMINISTRATION

N. T. A. CAMPKIN, J. R. HOOD AND S. A. FELDMAN

SUMMARY

We have compared the degree of tetanic fade relative to twitch depression occurring after isolated forearm block with vecuronium and that after systemic i.v. injection. Fifteen patients received either vecuronium 0.3 mg into an isolated forearm or vecuronium 0.05 mg kg^{-1} systemically. Adductor pollicis mechanomyography was used to monitor recovery of twitch height at 0.2 Hz. At 25, 50, 75 and 100% recovery of twitch height, a 5-s, 50-Hz tetanus was administered and tetanic fade ratio measured. There was significantly less tetanic fade in the isolated forearm group ($P < 0.01$; unpaired t test) at 25, 50 and 75% twitch height. This suggests that twitch depression and tetanic fade are independently mediated effects of vecuronium. (Br. J. Anaesth. 1993; **70**: 581–582)

KEY WORDS

Neuromuscular relaxants: vecuronium. Neuromuscular transmission: tetanic fade.

There is considerable evidence that twitch depression and fade produced by non-depolarizing neuromuscular blocking drugs are separate effects, mediated at different sites within the neuromuscular junction [1], although this model has been questioned recently [2, 3]. Bowman and Webb [4] noted that different techniques of drug administration in cats may produce different degrees of fade relative to twitch height, suggesting that the two effects are mediated independently. In this study, we investigated the degree of tetanic fade that is produced in the human adductor pollicis muscle using two different techniques of drug administration—systemic i.v. injection and isolated forearm block.

METHODS AND RESULTS

After obtaining approval by the Hospital Research Ethics Committee, we studied 15 consenting patients (ASA grade I or II), allocated randomly to one of two groups: group 1 = systemic vecuronium 0.05 mg kg^{-1}; group 2 = isolated forearm vecuronium 0.3 mg. The dose of vecuronium used in each group was selected to produce 100% twitch block and have a comparable duration of action to allow assessment of fade during recovery.

Patients with medical conditions or receiving drugs known to affect neuromuscular function were excluded. All patients received i.m. pethidine 1 mg kg^{-1} with promethazine 25 mg 1 h before operation. Anaesthesia was induced with i.v. propofol 2–3 mg kg^{-1} and maintained with propofol infused at 6–10 mg kg^{-1} h^{-1} and 60% nitrous oxide in oxygen. After administration of systemic vecuronium to patients in group 1, the trachea was intubated and the lungs ventilated to maintain end-tidal carbon dioxide tension in the range 4.5–5.5 kPa. Patients in group 2 breathed spontaneously via a nasopharyngeal airway.

The ulnar nerve at the right wrist (group 1) or both wrists (group 2) was stimulated supramaximally (0.2 Hz, 0.2 ms duration) via adhesive electrodes. The mechanical evoked response of the adductor pollicis muscle was measured using a modified 20-kg load cell taped to the hand with a preload of 200–300 g, and recorded on a paper chart recorder. After 10 min, a control tetanus (50 Hz for 5 s) was administered. Ten minutes later, in group 1, vecuronium 0.05 mg kg^{-1} was administered i.v. into the contralateral arm; in group 2, a pneumatic tourniquet was inflated to greater than arterial pressure on the patient's right forearm and vecuronium 0.3 mg diluted in 20 ml of saline was injected into a vein on the dorsum of this hand. In both groups, 100% twitch depression was produced in all cases. In group 2 the arterial tourniquet was deflated after 3 min. Neuromuscular block in both groups was allowed to recover spontaneously. At 25, 50, 75 and 100% of control twitch height, a tetanic stimulus (50 Hz for 5 s) was administered to each monitored hand in both groups. During tetanic stimulation, the gain and speed of the chart recorder were adjusted to enable recordings of the response to be made.

The ratio between the tension at the end of the 5-s tetanus to the maximum tension developed initially (tetanic fade ratio (TFR)) was calculated for each tetanus. The time to 25% recovery of twitch height (T_{0-25}) and the 25–75% recovery index (RI) also were

RI	9.7 (1.9)	7.4 (1.0)*
TFR		
Control	0.93 (0.01)	0.94 (0.01)
25%	0.27 (0.07)	0.78 (0.03)**
50%	0.35 (0.08)	0.86 (0.03)**
75%	0.52 (0.09)	0.89 (0.02)**
100%	0.80 (0.07)	0.92 (0.01)

measured for each patient. The TFR at each level of twitch recovery (T_{0-25} and RI) in the two groups were compared by unpaired Student's *t* test.

The groups were comparable in age and weight (table I). There was no significant difference between groups in T_{0-25}, indicating that the doses chosen were approximately equi-effective in terms of twitch depression. RI was significantly smaller in the isolated arm group ($P < 0.05$, unpaired Student's *t* test). There was no significant difference between the control TFR in each group. There was no depression of twitch response or tetanic fade produced in the contralateral hand of patients in group 2 after tourniquet release. At 25, 50 and 75% twitch recovery, there was significantly less tetanic fade in the isolated forearm of group 2 patients than after the systemic dose ($P < 0.01$).

COMMENT

In this study the same drug, administered in two different ways, produced differing degrees of tetanic fade relative to twitch depression, suggesting that the two effects are mediated independently. This finding supports that of Bowman and Webb [4], who observed that fade of the tetanic response to stimulation at 50 Hz in the cat soleus muscle was much less marked after block was produced by a small dose of tubocurarine administered i.a. than after similar twitch depression produced by a larger i.v. dose. Bowman [1] interpreted their findings as evidence that twitch depression and fade are consequences of separate actions of a competitive neuromuscular blocker; he postulated that less fade might be produced after arterial injection because there was less time for binding to "fade sites" to occur, as the drug was washed rapidly through the muscle and diluted in the general circulation. He also proposed [1] that a slower rate of binding to the fade sites would explain the different time course of twitch depression and fade observed clinically [5]. This explanation has been questioned, however [2, 3], by workers who have challenged the dual receptor hypothesis and consider that the different time course of fade and twitch depression may be a pharmacokinetic artefact. A slow rate of binding to fade sites would, however, explain the relatively little fade seen in the isolated forearm. In this technique, drug is concentrated in the muscle for 3 min before tourniquet release. This produces rapid onset of twitch depression, but may be inadequate time for binding to fade sites to occur.

After tourniquet release in the isolated forearm, the small dose of neuromuscular blocker is distributed to the general circulation. This produces no measurable effect in the contralateral arm, implying that the plasma concentration of drug is small during recovery. However, despite the small plasma concentration, depression of twitch height persists in the isolated forearm for a significant duration. In the present study, mean time for recovery to 75% twitch height was 25.2 min in the isolated forearm group, compared with 29.9 min in the systemic group. This slow recovery of twitch height in the isolated forearm is presumed to be caused by drug persisting in the biophase after tourniquet release, despite the small plasma concentration. In the absence of significant circulating drug, however, it appears that fade sites are not readily blocked by drug sustaining continued twitch depression by its persistence in the biophase. This again suggests that the sites for these two effects are distinct and may be subject to local factors affecting the ease of access and binding to each.

ACKNOWLEDGEMENT

Financial support was received from Charing Cross and Westminster Hospitals Trustees.

CASE REPORTS

ADULT RESPIRATORY DISTRESS SYNDROME AFTER ATTEMPTED STRANGULATION

P. G. MURPHY, R. JACKSON, R. KIROLLOS, J. S. GIBSON
AND P. CHENNELLS

SUMMARY

We describe a case of severe acute lung injury after attempted strangulation. The patient presented initially with cerebral irritability and florid, non-cardiogenic pulmonary oedema which were followed by a prolonged period of the adult respiratory distress syndrome, severe sepsis and multiple system organ failure, although the patient eventually survived. The pulmonary injury following strangulation is proposed to be a result of the generation of marked subatmospheric pressures within the lungs during vigorous inspiration against an obstructed airway, although the processes involved in the so-called neurogenic pulmonary oedema are difficult to exclude. (Br. J. Anaesth. 1993; **70**: 583–586)

KEY WORDS

Lung: adult respiratory distress syndrome.

Many factors, chemical, physical and biological, have been associated with the evolution of the adult respiratory distress syndrome (ARDS) [1, 2]. The expanded definition of ARDS [3] requires exposure to a process or pathology *recognized* to be associated with the condition. Mechanical asphyxiation has not been specifically identified as a cause of ARDS. In this report, we describe the evolution of ARDS and multiple organ failure in a patient asphyxiated by manual strangulation.

CASE REPORT

A 30-yr-old Caucasian female was admitted to our Accident and Emergency Department after an anonymous telephone call to the emergency services. She was restless, opisthotonic and unresponsive; the admission Glasgow Coma Scale (GCS) score was 7 ($E_4V_2M_1$). She was normotensive (systolic/diastolic pressure 120/90 mm Hg), tachycardic (heart rate 150 beat min^{-1}) and reasonably well oxygenated, breathing oxygen-enriched air via a simple face mask (Sp_{O_2} 95%, Pa_{O_2} 13.0 kPa). She was tachypnoeic, however, with a marked stridor and fine inspiratory râles in both lung bases. Ecchymoses and petechial haemorrhages were noted on the neck, cheeks, forehead and sclera, the soft palate was congested and bilateral papilloedema noted. Fresh bruising and linear scratches, but no ligature marks, were seen on the neck. A diagnosis of attempted manual strangulation was made, and in view of the evident significant diffuse cerebral insult and the possibility of upper airway injury, the trachea was intubated and the lungs ventilated. After a rapid sequence induction using fentanyl 250 µg, etomidate 20 mg and suxamethonium 100 mg, the trachea was intubated easily with an 8.0-mm cuffed tracheal tube, although haemorrhagic supraglottic oedema was noted. Profuse, blood-stained pulmonary oedema was observed soon after intubation, and the patient was transferred to our Intensive Care Unit for further management. The subsequent clinical events have been divided into three epochs, and described semi-quantitatively using the APACHE II [4] and acute lung injury scoring [3] systems (fig. 1).

Days 1–3. The prominent features of this initial period were acute respiratory failure and cardiovascular instability. Florid pulmonary oedema was associated with diffuse patchy opacification and bilateral pneumothoraces visible on the chest x-ray (fig. 2A). Satisfactory oxygenation was only achieved by positive pressure ventilation with inspired oxygen fractions of up to 0.8, and positive end-expiratory pressure of 5–10 cm H_2O. More refractory to treatment was the systemic hypotension, which failed to respond to inotropic agents (dobutamine 20 µg kg^{-1} min^{-1}) and which improved only after infusion of 2500 ml of colloid. The site for such apparent volume loss was not clear: there were no long bone or pelvic fractures, abdominal lavage was negative and an ultrasound failed to demonstrate any hepatic, renal or splenic injury, although significant and unexpected ascites was demonstrated (fig. 2B). The considerable pulmonary oedema (which, together with the ascites, appeared responsible for the initial hypovolaemia) was persistently associated with a pulmonary artery wedge pressure less than 15 mm Hg, suggesting that it was non-cardiogenic in origin.

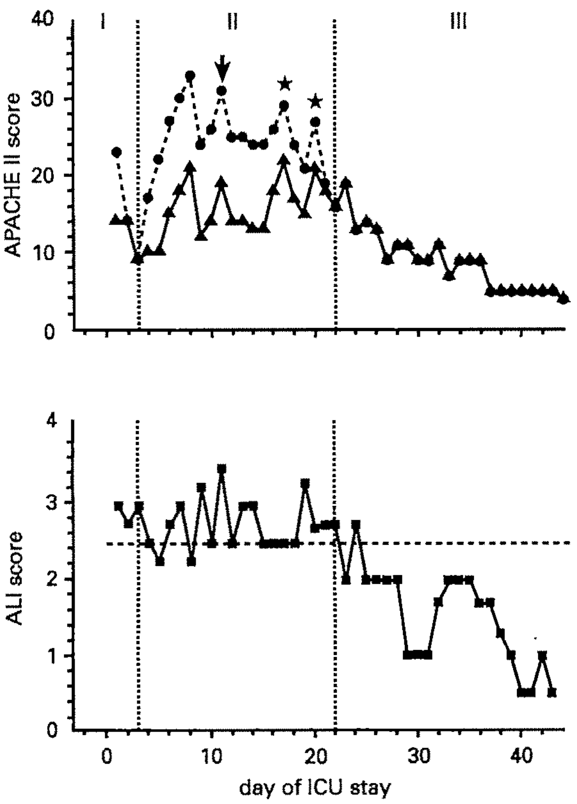

FIG. 1. APACHE II and acute lung injury (ALI) scores. The clinical course has been divided into three epochs: 1 = acute lung injury; II = ARDS and multiple organ failure; III = recovery (see text for details). APACHE II data are presented with (●) and without (▲) the contribution of the Glasgow Coma Scale score. Severe pulmonary injury is defined as an ALI score > 2.5. The deterioration in lung function on days 32–38 reflected a second period of pulmonary oedema, on this occasion as a result of fluid overload. ↓ = Administration of methylprednisolone and Centoxin; *coagulase-negative staphylococcal septicaemia.

Although the patient was awake and orientated the day after the assault, gas exchange was still sufficiently impaired to prevent weaning from artificial ventilation (the acute lung injury (ALI) score remaining greater than 2.5—the score at which lung injury is said to be severe [3]).

Days 4–22. In this second phase, persisting severe lung injury (ALI score > 2.5) was associated with non-pulmonary organ failure. Repeated episodes of severe sepsis suggestive of Gram negative septicaemia (pyrexia > 38.5 °C, cardiac index 5–6 litre min^{-1} m^{-2}, systemic vascular resistance index 450–700 dyn s m^2 cm^{-5}) were observed, but always without any microbiological identification of the responsible organism. Despite minimal sedation, conscious level deteriorated, so that the APACHE II scores, including a GCS component, were particularly increased. Persistent ileus prevented successful enteral nutrition; total parenteral nutrition was therefore required. A striking thrombocytopenia developed ($< 50 \times 10^{12}$ $litre^{-1}$), with increased concentrations of bilirubin (> 100 μmol $litre^{-1}$) and aspartate aminotransferase (70–272 iu $litre^{-1}$ (normal range 10–40 iu $litre^{-1}$)), and increased prothrombin ratio (1.4–1.9, days 2–12) suggesting modest liver disturbance. Renal function remained satisfactory throughout.

By day 11, the ALI score reached its peak value of 3.5. Bilateral pulmonary air leaks persisted with conventional positive pressure ventilation, but satisfactory oxygenation could not be maintained using high frequency jet ventilation. Core temperature (measured with the pulmonary artery flotation catheter) reached 41.6 °C and again a severe septicaemic-like haemodynamic profile was noted without any further evidence of Gram negative infection. In view of the severity of the patient's condition, it was felt necessary to treat several possibilities empirically. Thus the patient received methylprednisolone 2 g, a combination of broad spectrum antibiotics together with Centoxin 100 mg (monoclonal antibody to bacterial lipopolysaccharide, Centocor). As shown by the trend in the APACHE II scores,

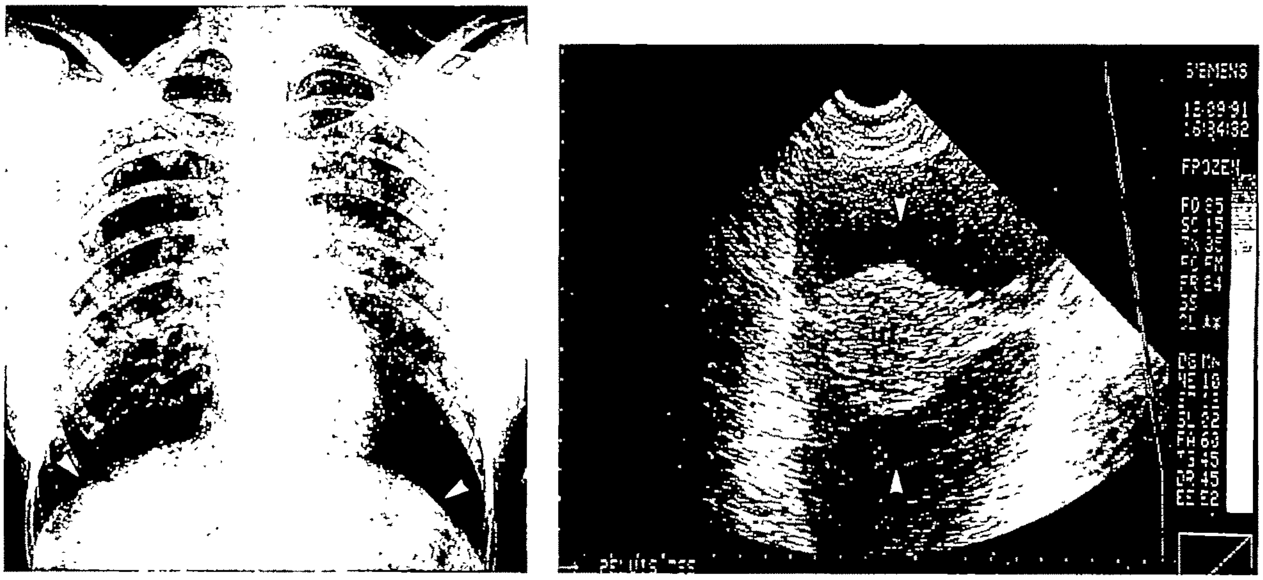

FIG. 2. Supine antero-posterior chest x-ray (left) and transverse section pelvic ultrasound (right) performed on the day of admission. The chest x-ray demonstrates florid pulmonary oedema and bilateral pneumothoraces (arrowed). The pelvic ultrasound scan shows the uterus (ut) floating in a significant quantity of ascites (arrowed).

from this point onwards the general trend was one of improvement, twice interrupted by episodes of coagulase-negative staphylococcal septicaemia (asterisks in figure 1) successfully treated with vancomycin. Conscious level improved also, as shown by the convergence of the APACHE II scores with and without the GCS score. High frequency jet ventilation was introduced successfully on day 17, and allowed the bronchopleural fistulae to heal.

Days 22–44. This third period was one of recovery. The patient was fully orientated and without any focal neurological defect. Enteral feeding was introduced successfully and the patient gradually weaned from artificial ventilation (although a continued susceptibility of the lungs to fluid overload was responsible for the deterioration in ALI score in days 31–35). The patient was transferred to a rehabilitation ward 44 days after admission to our Intensive Care Unit, and was discharged home after a total of 127 days in hospital.

DISCUSSION

The forensic features of fatal manual strangulation depend principally upon whether death occurs rapidly from vagally mediated cardiac arrest (as a result of intense carotid body/sinus stimulation), or more slowly from the combined effects of hypoxia (caused by upper airway obstruction) and intracranial hypertension (which develops when the venous drainage, but not the arterial supply, of the head is obstructed) [5]. The patient described in this case report displayed many of the features of the so-called *hypoxic* form of manual strangulation. The bruises and linear scratch marks around the neck relate to the assailant's attack itself, whilst the various manifestations of venous congestion in the head and neck (including supraglottic oedema and papilloedema) suggested significant jugular venous hypertension. It is not clear, however, if the acute brain injury seen at presentation could be explained by venous hypertension alone, or if cerebral hypoxia or ischaemia contributed.

The pulmonary consequences of fatal mechanical asphyxiation include acute focal emphysema and florid haemorrhagic pulmonary oedema. These features suggest an increase in the permeability of the alveolar–capillary barrier, and have been used to identify the cause of death in a series of homicides in which there was no external evidence of asphyxiation [6]. The florid pulmonary oedema with which this patient presented was associated with a normal pulmonary artery wedge pressure, suggesting that it was non-cardiogenic in origin. Some workers have proposed that the disruption of the alveolar–capillary barrier after asphyxiation is a consequence of the marked subatmospheric pressures developed within the lungs during forced inspiration against an obstructed upper airway [5, 6]. In this regard, this form of lung injury is similar to the well described phenomenon of pulmonary oedema after relief of upper airway obstruction associated with anaesthesia, laryngospasm, tumours, foreign bodies and goitre [7]. Other workers have shown that (experimental ligature) strangulation is associated with an intense, neurohumorally-mediated vasoconstriction which they propose may damage the pulmonary, renal and splanchnic microcirculations [8–10]. Intense pulmonary hypertension is also a frequent feature of neurogenic pulmonary oedema, although in this condition an increase in the permeability of the pulmonary microcirculation is thought to be a more fundamental pathophysiological feature, with increased pulmonary capillary pressure serving only to exacerbate alveolar flooding [11]. Either (or both) mechanisms could explain the florid pulmonary oedema seen in the early stages of this case, although the significant ascites with which this was associated suggests a process not restricted to the pulmonary microcirculation alone.

The progression to a protracted period of severe sepsis and multiple organ failure, (dominated by severe ARDS but accompanied by brain failure, persistent ileus, hepatic and bone marrow dysfunction), was unexpected and not described in a previous case report of pulmonary oedema after attempted strangulation [12]. It is tempting to attribute this to the release of toxins and microorganisms into the systemic circulation from a "leaky" gastrointestinal tract. Experimental ligature strangulation is known to disrupt the splanchnic circulation [10], and the marked ascites seen in this patient points to a similar disruption. In addition, sustained improvement was *associated* with the administration of methylprednisolone and a monoclonal antibody to bacterial lipopolysaccharide, both of which might interfere with various stages of the inflammatory pathways of severe sepsis [13].

The expanded definition of ARDS views acute lung injury as part of a spectrum of multiple system organ failure [3]. It requires that, in addition to identification of severe lung injury, there should also be evidence of non-pulmonary organ failure, with a history of clinical disorder or insult recognized to be associated with the evolution of the condition. It is not clear if, given these criteria, the term *ARDS* could be applied to the patient's initial condition, although there is no doubt that the lung injury was severe. In contrast, the later stage of established severe lung injury and multiple system organ failure clearly qualified as ARDS, although strangulation is not a recognized cause. We propose that strangulation (and possibly other forms of mechanical asphyxiation) should be considered as physical insults capable of causing severe acute lung injury and ARDS.

ANAESTHETIC IMPLICATIONS OF THE ANTI-CARDIOLIPIN ANTIBODY SYNDROME

G. MENON AND J. ALLT-GRAHAM

SUMMARY

The anti-cardiolipin antibody syndrome (or anti-phospholipid antibody syndrome) is characterized by the presence of autoantibodies to phospholipids. Its major association is with systemic lupus erythematosus. It is characterized further by in vitro *prolongation of phospholipid-dependent coagulation tests. However,* in vivo *it is associated with a markedly increased incidence of thrombosis, both arterial and venous. We describe the case of a 36-yr-old female patient with the anti-cardiolipin antibody syndrome who presented initially for diagnostic laparoscopy and later for exploratory laparotomy. Her postoperative course after the first general anaesthetic was complicated by disseminated intravascular coagulation and adult respiratory distress syndrome. After the second operation, she deteriorated further with worsening cardiac, renal and respiratory function and eventually died. As far as we are aware, this is the first reported case of the anti-cardiolipin antibody syndrome in anaesthetic literature. Further aspects of this puzzling condition and its anaesthetic implications are discussed.* (Br. J. Anaesth. 1993; **70**: 587–590)

KEY WORDS

Complications: anti-cardiolipin antibody syndrome.

The anti-cardiolipin antibody syndrome is characterized by the presence of anti-phospholipid antibodies in patients who show a tendency to recurrent thromboses (both arterial and venous), recurrent abortions, thrombocytopenia and neurological disease [1, 2]. The term "cardiolipin" is derived from the antigen used to test for these antibodies which utilizes a lipid component of bovine heart tissue [3]. The syndrome has been described by several authors [4, 5].

The exact role of these antibodies in the syndrome is uncertain. There is a controversy in the medical literature as to whether they are aetiological agents of pathogenesis or if they are just simple markers of a high-risk population [6]. About 50% of patients with this syndrome have systemic lupus erythematosus (SLE). Others may have other connective tissue diseases (e.g. scleroderma). The prevalence of these anti-phospholipid antibodies in patients with SLE has been estimated, at various times, as 5–55% [7, 8].

These patients may present to the anaesthetist for routine and emergency operations, and in the intensive care unit. In addition, as SLE occurs primarily in women in the childbearing age group, with a female:male ratio of approximately 10:1, there is a greater incidence in obstetric patients [9]. The anaesthetist may be involved in the care of these high risk parturients, especially as operative delivery is common. The anaesthetic literature lacks any references on this subject. We present a case report of this condition.

CASE REPORT

A 36-yr-old Indonesian female, gravida 2, para 0, presented to the gynaecologists with a 1-week history of lower abdominal pain, high grade pyrexia and a brief episode of vaginal bleeding. An ultrasound scan demonstrated a pelvic mass consistent with a necrotic ovarian tumour. SLE had been diagnosed 10 years earlier ("lupus like", rather than classical SLE). She was receiving warfarin 3 mg and aspirin 75 mg daily. There was a history of a stroke in the past, but the patient was unable to provide further details because of her and her family's inability to speak English. There were no residual signs of a stroke except for partial blindness in one eye. In addition, her old notes from another hospital were not available at the time. Investigations revealed a haemoglobin concentration of 8.0 g dl^{-1} and a greatly prolonged prothrombin time (PT) and activated partial thromboplastin time (APTT), with normal platelets. Before diagnostic laparoscopy, the warfarin was stopped and the coagulation profile corrected with fresh frozen plasma (FFP) to bring the International normalized ratio within the therapeutic range. Anaesthesia was induced with thiopentone and suxamethonium and maintained with enflurane, fentanyl and vecuronium. Laparoscopy confirmed the presence of a large ovarian fibroma or a sub-serous fibroid.

After operation in the recovery room, the patient was clinically stable, but developed significant hypoxaemia when oxygen was discontinued. Oxygen therapy was re-commenced and she was transferred back to the ward. In the ward, anticoagulation was

---

G. MENON, M.B., B.S., F.R.C.ANAES.; J. ALLT-GRAHAM, M.B., B.S., B.SC., F.F.A.R.A.C.S., F.R.C.ANAES.; Department of Anaesthetics, St George's Hospital, Blackshaw Road, Tooting, London SW17 0QT. Accepted for Publication: November 24, 1992.

recommenced with heparin infusion. The patient developed further hypoxaemic episodes in the ward over the next 1 week, accompanied by pleuritic chest pains and shortness of breath. However, ventilation–perfusion scans were not consistent with pulmonary embolism. She continued to have persistent pyrexia (> 39 °C) while receiving broad spectrum antibiotics. All investigations for the cause of the fever were inconclusive (blood cultures, viral serology, malarial parasites etc.).

At this point, the patient's old notes became available from another hospial. The records revealed a significant history of major thrombotic episodes. Aged 20 yr, the patient had developed sudden unexplained venous thrombosis of her left leg. At the age of 26 yr, after an appendicectomy, she developed retinal vein thrombosis. Investigations led to a diagnosis of SLE although she was anti-nuclear antibody negative. At the age of 32 yr, when 27 weeks pregnant, she underwent emergency Caesarean section under general anaesthesia. Three days post-partum she developed a brain-stem infarct. At this time, she was found to be strongly anti-cardiolipin antibody positive and anticoagulation was commenced with warfarin. Her next presentation was at the age of 35 yr when, after dilatation and curettage for a miscarriage, she developed a cerebellar infarct.

In the light of this history of major thrombotic events and a diagnosis of the anti-cardiolipin antibody syndrome now available, full heparinization was continued. In spite of this, the patient deteriorated further with continuing high pyrexia, becoming semi-conscious with neck stiffness and a blood picture suggestive of disseminated intravascular coagulation. CT scan of the head demonstrated old cerebellar and basal ganglia infarcts, but no new changes. The cause of her sudden neurological deterioration was unclear. High-dose steroid therapy was started and antibiotics were continued.

The patient was admitted to the intensive care unit for monitoring of her cardiovascular and neurological state. She made a rapid neurological recovery with resolution of neck stiffness and recovery of full consciousness. However, she remained tachycardic (> 150 beat min^{-1}), pyrexic (> 39 °C), tachypnoeic and hypoxaemic. Echocardiogram was normal. While receiving full heparinization, the patient developed further episodes of pleuritic chest pain. Plasmapheresis was commenced to decrease her concentration of anti-cardiolipin antibody. She continued to deteriorate, with decreasing renal and respiratory function. A pulmonary artery thermodilution catheter was inserted and revealed a central venous pressure of 9 mm Hg, pulmonary artery pressures of 30/18 mm Hg, pulmonary artery wedge pressure of 19 mm Hg, and cardiac index of 1.2. A repeat echocardiogram (within 24 h of the previous one) revealed a large, poorly functioning left ventricle with poor global systolic contraction. Treatment with inotropes and vasodilators (dopamine, dobutamine, adrenaline, nitrates) produced some improvement in cardiac index. In view of the patient's deterioration and intra-abdominal signs suggestive of a necrotic ovarian/uterine fibroid, it was decided to proceed to exploratory laparotomy.

Heparin was stopped 2 h before operation and anaesthesia induced in the operating theatre with full haemodynamic monitoring. A rapid-sequence induction was performed with etomidate and suxamethonium and anaesthesia maintained with atracurium and incremental doses of fentanyl. The intraoperative course was uneventful. The patient remained haemodynamically stable, with good gas exchange. Laparotomy confirmed the presence of a necrotic ovarian fibroid which was removed. Blood loss was estimated at 300 ml. However, in view of the continuous oozing and decreasing haemoglobin concentration, she was transfused with 1 unit of blood, 6 units of platelets and 2 units of FFP.

The patient was transferred back to the intensive care unit after operation, with full circulatory and ventilatory support. On arrival in the unit, she developed increasing facial oedema with mottled, blueish macular discolouration of the skin and congested neck veins. However, central venous pressure and lung inflation pressures were normal and an echocardiogram did not reveal any new changes. There were no signs of superior vena cava obstruction or cardiac tamponade. Blood-gas analyses revealed severe metabolic acidosis, but normal gas exchange.

Her general condition continued to deteriorate with worsening renal, cardiac and respiratory function in spite of haemodyalysis, full inotropic support and continued ventilation. She died 10 days after admission for the initial complaint.

Postmortem revealed only the presence of numerous scattered petechial haemorrhages over the myocardium with left ventricular hypertrophy. The coronary arteries were normal. The cause of death was recorded as cardiac failure. There was pulmonary oedema in the lungs, but no evidence of infarct or emboli. Apart from old infarcts in the basal ganglia and cerebellum, the rest of the postmortem examination was unremarkable.

DISCUSSION

The unfortunate demise of this patient prompted us to search the anaesthetic literature on the anaesthetic implications of the anti-cardiolipin syndrome. We were unable to find any information on this subject, apart from one reference to the lupus anticoagulant [10]. A search of the general medical literature revealed a large number of conflicting facts, reports and ideas [1–8].

The anti-cardiolipin antibodies may be part of a family of autoantibodies. A cause and effect relation between presence of antibodies and complications has not been established. About 50% of patients with this syndrome have SLE, although the prevalence of these antibodies in SLE patients may vary from 5 to 55% [7, 8].

Patients with this syndrome who have SLE are usually "lupus like" [11]. The revised American Rheumatism Association criteria for diagnosis of classical SLE requires the presence of four or more typical symptoms (e.g. malar rash, arthritis, photo-sensitivity, renal involvement) [12]. Most of the patients with classical SLE (> 90 %) are antinuclear antibody (ANA) positive. Patients who have fewer than four of the above criteria are labelled "lupus-like" and are usually ANA negative (similar to our patient).

The diagnosis of this syndrome is confirmed by specific tests:

(a) The presence of these antibodies blocks the activity of the X_a–V_a–Ca^{2+} phospholipid complex required to convert prothombin to thrombin. *In vitro*, the phospholipid-dependent coagulation tests (APTT and kaolin cephalin clotting time (KCCT)) are prolonged, although prothrombin time (PT) and thrombin clotting time are usually normal.

(b) The most sensitive and specific test for the presence of the anti-cardiolipin antibodies is an enzyme-linked immunosorbent assay (ELISA) [13]. The combination of these two tests gives the greatest degree of sensitivity and specificity.

In vivo, these patients have a markedly increased incidence of thromboses. There are many theories on the aetiology of thromboses, but so far none has been substantiated. Current knowledge suggests that these antibodies mediate thrombosis by acting at several sites of action. When platelets are pre-activated by a variety of stimuli, they expose the negatively-charged phospholipids on their surface to the antibodies, resulting in platelet aggregation.

The antibodies also react with surface phospholipids in endothelial cells, inhibiting the production of prostacyclin and interfering with the action of thrombomodulin and protein C in endothelial cells. Thus platelet aggregation is promoted. The clinical manifestations of platelet aggregation and thrombosis could lead to thrombocytopenia [8].

In 40–50 % of patients with this syndrome, there is a history of *thromboses*, both arterial and venous, often recurrent, at unusual sites and occurring spontaneously. This picture was typical of our patient. The venous system involved may be at unusual sites such as the renal, retinal and adrenal venous systems. In addition, one case of superior vena caval occlusion in anti-cardiolipin antibody syndrome has been described [14]. Our patient developed a similar picture after operation, with increasing facial oedema and congested neck veins. Venography to confirm thrombosis is not recommended in these patients.

The obstetric history may show recurrent spontaneous *abortions*. Presence of circulating anti-cardiolipin antibodies is associated with increased fetal loss in all trimesters and approaches 80 % in patients with high titres of antibodies. This was again typical of our patient. The presence of the anti-cardiolipin syndrome in patients with SLE makes the pregnancy a high-risk one. There is an increased incidence of pre-eclamptic toxaemia in patients with this syndrome [15].

A prospective study looked at the incidence of cardiac complications in patients with SLE with and without the anti-cardiolipin antibody syndrome [16]. There was a 54 % incidence of cardiac complications in the SLE group. However, in the presence of SLE and the anti-cardiolipin syndrome, the incidence was close to 80 %. The myocardial changes seen in our patient were those characterized in this study—global and left ventricular dysfunction.

Neurological complications in the anti-cardiolipin antibody syndrome comprise transient ischaemic attacks, strokes and neuropsychiatric disturbances [17]. Our patient showed such a picture, with a sudden neurological deterioration followed by recovery.

In addition, there is another presentation described recently [18], with acute, widespread, non-inflammatory vascular occlusions resulting in major organ dysfunction. The trigger factor seems to be infection, changing the anticoagulation regimen, or both [19]. Patients with this syndrome have a tendency to develop thromboses even while receiving full anticoagulation. Our patient had classical signs suggestive of multiple pulmonary emboli even while receiving full heparinization.

Patients with SLE present a significant morbidity and mortality. The 5-yr survival rate is approximately 75 %. The morbidity and mortality is increased substantially in the presence of the anti-cardiolipin antibody syndrome, although no figures are available as yet.

We recommend the following management regimen in patients with the anti-cardiolipin antibody syndrome:

All patients with SLE and a history of recurrent abortions, thrombotic episodes, or both, should be screened for the antibody. If positive, and in the presence of high titres, the complications are increased substantially.

In patients with SLE and in the presence of anti-cardiolipin antibodies but with no history of thrombosis and a normal coagulation screen (except for prolonged APTT), appropriate s.c. preoperative doses of unfractionated heparin or low molecular weight heparin are recommended.

Patients with a history of one or more thrombotic events require permanent anticoagulation and there should be close liaison with haematologists for this purpose. It is important to maintain these patients in their anticoagulated state, with warfarin or aspirin. In the perioperative period, carefully controlled heparin therapy by infusion or given s.c. is recommended.

Regional anaesthesia is generally contraindicated in patients receiving high-dose warfarin. The use of regional techniques in those receiving low-dose aspirin, even with a normal bleeding time, is debatable. The safety of regional blocks in a patient who has the anti-cardiolipin antibody syndrome and prolonged APTT is unknown. The use of regional techniques in the uncomplicated syndrome is probably not associated with any complications. Regional techniques would naturally be contraindicated in the presence of an overt coagulopathy, decreased platelet concentrations, or both.

Patients who have the diffuse coagulopathy, vasculopathy picture (of our patient) need intensive haemodynamic monitoring in the intensive care unit with plasmapheresis (to decrease the titre of the anti-cardiolipin antibody), high-dose steroids, full heparinization and, if disseminated intravascular coagulation is present, appropriate replacement. In the presence of a circulating anticoagulant, the adequacy of heparinization is monitored preferably with a heparin assay.

From this case history and available literature, the following anaesthetic recommendations would seem appropriate:

(a) All prophylactic measures should be taken to prevent thromboses. Use of anti-embolic stockings, avoiding dehydration and maintaining normothermia should be mandatory.

(b) Drugs likely to precipitate or exacerbate the condition (e.g. hydralazine) should be avoided.

(c) Infection, which is another trigger source for lupus and for initiating coagulopathy, should be prevented by routine antibiotic therapy.

(d) Blood transfusion should be avoided if possible, as this has also been implicated as a trigger factor.

(e) Standard monitoring (heart rate, oximetry, capnograph, ECG, etc.) may be all that is needed for routine cases. In addition, patients may need CVP/pulmonary artery monitoring in the presence of severe cardiac, renal or pulmonary artery involvement.

(f) Postoperative hypoxaemia, when it occurs, may be indicative of ARDS or pulmonary thromboembolism and needs investigation and monitoring in an intensive care unit. If signs of acute widespread coagulopathy occur, early aggressive plasmapheresis with high-dose steroids and immunosuppression may be indicated.

ACKNOWLEDGEMENT

We thank Dr Parker-Williams, Consultant Haematologist, St George's Hospital for his advice.

SPONTANEOUS REPOSITION OF A DISLOCATED ARYTENOID CARTILAGE

A. GAUSS, H. S. TREIBER, J. HAEHNEL AND H. S. JOHANNSEN

SUMMARY

We report a patient suffering from arytenoid cartilage dislocation after difficult tracheal intubation and the abrupt spontaneous reposition in the course of severe vomiting 1 month after the operation. Predisposing factors for the unusual reposition are discussed. (Br. J. Anaesth. 1993; **70**: 591–592)

KEY WORDS

Complications: arytenoid dislocation. Intubation, tracheal.

Arytenoid dislocation is a rare event and complication of tracheal intubation [1–11]. It may cause the following changes: alteration in vocal quality (weak voice, whisper, hoarseness, aphonia) [3, 5, 8–10], diminished airway (stridor) [2, 6, 8, 11], sore throat, or painful swelling [1].

Laryngoscopy reveals an immobile vocal cord. Correct diagnosis is essential, to exclude neurogenic vocal cord paralysis, as the management of the two conditions is different. Early reposition of the dislocated arytenoid is required when dislocation has occurred.

CASE REPORT

A 60-yr-old man was scheduled for radical prostatectomy and was classified ASA II. He reported a chronic dry cough for several years, but an ENT examination 6 months earlier had not revealed any pathology except what was described as a hypersensitive bronchial system. In the past, he had undergone three general anaesthetics, one with intubation 21 yr previously. Difficulty with intubation was not expected, as the Mallampati classification was I [12], with mouth opening 5 cm.

Anaesthesia was induced and laryngoscopy, performed with a No. 3 MacIntosh blade, was difficult. It was classified as Cormack grade 3 [13] (epiglottis only visible), and accomplished by an experienced senior registrar at the first attempt with a 8.5-mm i.d. super-safety-tube (34 CH, Ruesch, Germany) using a stylet. The tip of the tube was easily pushed down around the stylet lying in the trachea and rotation of the tube was not required. With the exception of a bradycardia of 40 beat min^{-1} after administration of suxamethonium and during intubation, there was no other anaesthetic or operative problem. A nasogastric tube (14-gauge) was passed without difficulty at the time of intubation. Because of hypothermia at the end of surgery, mechanical ventilation was continued for 8 h after operation. At 12 h after tracheal intubation, the trachea was extubated without difficulties, with the tube cuff deflated.

On the first day after operation the patient complained of feeling a bolus in the throat. ENT examination on the same day revealed distinct oedema of the soft palate on both sides, with unremarkable larynx and vocal cords.

Follow-up examination by another otorhinolaryngologist showed "a discreet oval-shaped insufficiency of the closure of both vocal cords," but no signs of trauma caused by tracheal intubation. The continuing aphonia of the patient was suspected to be caused partially by his chronic obstructive bronchitis.

A third ENT consultation described paresis of the right vocal cord with normal mobility of both cricoarytenoid junctions, no haematoma and no inflammation.

Three weeks later, examination under local anaesthesia and review of the recent videoendoscopy revealed dislocation of the left arytenoid cartilage.

The previous differences in diagnosis were explained by the difficulties in laryngoscopy in this patient and his tendency to choke on examination.

Reposition of the cartilage under general anaesthesia was planned for the 26th day. Laryngoscopy revealed Cormack grade 3, confirmed by a second registrar, but repositioning could not be performed because of reduced mobility of the patient's head. Repositioning under local anaesthesia was scheduled subsequently, but not carried out because in the meantime, the patient was admitted to a different hospital with symptoms of pancreatitis and biliary colic. At that time aphonia persisted, but after a severe bout of vomiting, his voice changed abruptly to normal.

Final examination under indirect microlaryngoscopy revealed no dislocation of the arytenoid cartilage. The patient was content and did not notice any difference in his voice compared with time before the incident. Stroboscopy of the vocal cords was normal.

DISCUSSION

In our patient, tracheal intubation, using a stylet, was difficult and the vocal cords and arytenoid cartilages were not seen. Insertion of the nasogastric tube and tracheal extubation were performed without difficulty and tracheal extubation occurred 8 h after operation (short-term intubation). Consequently, we believed that the persisting aphonia was a direct result of tracheal intubation and, after several laryngological examinations, the cause of the aphonia was found to be dislocation of the left arytenoid cartilage.

Review of the literature indicates that, the left side is involved in the majority of cases of arytenoid dislocation [1, 3, 5–10]. We agree with Quick and Merwin [1] that the left arytenoid is at greater risk of the injury.

There are several possible causes of dislocation of the arytenoid. In our patient, the most likely explanations are either dislocation by pressure from the tip of the tube or the stylet [2] or trapping of the arytenoid between the stylet and the tube. A further explanation suggested by Quick and Merwin [1], although less likely in our patient, is the force exerted by the convex curvature of the distal third of the tracheal tube on the arytenoid cartilage.

To avoid trauma to the arytenoids, it might have been helpful to rotate the tube 90° anticlockwise before it approached the larynx, as proposed by Cossham [14].

Diagnosis may have been made earlier using computed tomography [8], especially in our patient, in whom direct and indirect examination of the larynx was not easy to perform and led to several misinterpretations. Oedema or haematoma of the cricoarytenoid region may also have delayed correct diagnosis [4, 7].

Arytenoid cartilage dislocation after tracheal intubation is uncommon, probably because of the wide range of passive motion allowed by the cricoarytenoid joint [1]. Habitual dislocation [15] can be excluded in this case, as our patient experienced no such event during previous tracheal anaesthesia. It is possible that chronic bronchitis with frequent coughing may cause loosening of the cricoarytenoid joint ligaments, thereby making possible dislocation of the arytenoid cartilage and its abrupt spontaneous reposition by comparatively minor forces [2].

The first case of spontaneous repositioning was reported by Rudert [7]. It occurred while his patient was coughing after accidentally aspirating a piece of an apple. Another case of spontaneous repositioning of bilateral dislocated arytenoids was reported by Chatterji, Gupta and Mishra [11]; restoration of the arytenoids to their normal position was associated with violent coughing. Here we present the third case of spontaneous repositioning of an arytenoid dislocation. The dislocation was caused by tracheal intubation and its spontaneous reposition occurred in the course of severe vomiting. The predisposing factor for this unusual reposition was probably chronic bronchitis.

CORRESPONDENCE

"CONCORDE NOSE" IN WHITACRE SPINAL NEEDLES

Sir,—We wish to report a complication of the 25-gauge Vygon Whitacre spinal needle in two patients.

A 72-yr-old ASA II female with a fractured right neck of femur presented for insertion of Pugh nail under spinal anaesthesia. She was placed in the left lateral position and, under aseptic conditions, a 25-gauge Vygon Whitacre needle was inserted via an introducer at the L3–L4 interspace. However, the needle struck bone and was immediately withdrawn. The resulting damage to the tip of the spinal needle is demonstrated on the lower right needle in figure 1.

A 27-yr-old ASA I female was to undergo elective Caesarean section. She was placed in the left lateral position and a 25-gauge Vygon Whitacre needle was advanced slowly at the L2-3 interspace. Firm resistance was felt and the needle could not be advanced any further. The needle was removed and the tip found to be distorted as shown in figure 1 (upper left needle).

Similar bending of the tip is a potential problem with Sprotte needles. In the U.S.A., it is recommended that, if the Sprotte needle tip is bent after encountering bone, the needle should be removed and not re-used [1].

The visible distortion of the atraumatic tips may result in increased tearing of dural fibres and possible increase in incidence of postdural puncture headache. If a Whitacre needle with a bent distal tip is re-used, there is also a risk of fracture of the tip, with possible infective and neurological sequelae. We suggest that, if a Whitacre needle strikes bone, the needle should be removed and discarded and a substitute needle inserted.

PERIPHERAL NERVE DAMAGE AND REGIONAL ANAESTHESIA

Sir,—The paper of Rice and McMahon elegantly illustrates the point that fine-bore needles inserted into isolated rat sciatic nerves are capable of producing significant and protracted damage [1]. There are some anecdotal clinical data to support this view [2]. As a consequence, the aim of most people who use local anaesthetic blocks is not to penetrate the nerve [3–6]. Because of the relative advantages of local anaesthetic blocks over other techniques [7], and the possibility of prolonged postoperative analgesia [8], it is important that we strive to reduce the risk of intraneural injection as opposed to abandoning local anaesthetic blocks *per se*.

The guidelines for local anaesthetic blocks need re-examination; to that end we are in agreement with the editorial by Chambers [9]. A particular issue is the suggestion that local anaesthetic blocks should not be used in anaesthetized or sedated patients. Is it not possible that most patients would respond to painful intraneural injections in the presence of light sedation/anaesthesia? In our experience, they often withdraw in response to cold antiseptic used on the skin. Therefore, should we stop using local anaesthetic techniques in sedated and anaesthetized patients in response to one poorly described case report of median nerve injury after a wrist block under general anaesthesia? There are many other instances of nerve injury unrelated to local anaesthetic techniques [10, 11].

Despite the evidence of Rice and McMahon [1], we feel that long-bevelled cutting needles should not be used. Some 75% of anaesthetics in this hospital are supplemented by local anaesthesia, and complications have occurred only in patients in whom long-bevelled needles have been used in relatively fixed nerves. Does the risk of intraneural injection still exist if: 1) nerves are not fixed within the surrounding tissue—such as the brachial plexus [12, 13], and probably the ulnar and median nerves at the elbow; 2) a nerve stimulator, short-bevelled needle and care are used? In our clinical experience using such techniques, we have never had evidence to suggest intraneural penetration in either awake or sedated patients. Is the risk worth taking of using long-bevelled needles together with paraesthesiae, when several publications have demonstrated that paraesthesia techniques are not superior to nerve stimulator techniques [3, 14], and long-bevelled needles are obviously sharper and thus more likely to penetrate the nerve?

Sir,—We thank Drs Baranowski and Buist for their interest in our paper and the accompanying editorial. For the record: nerve penetration occurred *in vivo* and nerves were not "isolated", in contrast with a previous study [1]; also the needles were not "fine-bore", but standard injection needles.

We examined the consequences of accidental penetration of nerve fascicles and demonstrated that, in this respect, long bevels were superior to short. We agree totally that all efforts should be made to prevent fascicle penetration, and hope all anaesthetists exercise "care" when performing regional anaesthesia, whatever their technique. However, as we stated, there are many other factors involved in needle-induced nerve injury—for example, the ability of different nerve needle bevels to penetrate nerve fascicles in clinical practice. As this area is supported at present only by the type of anecdotal evidence which Baranowski and Buist quote, definitive comment is precluded until substantive data are available. However, it is salutary to note that Sjöström and colleagues [personal communication, 1992] have used long-bevelled needles for more than 17000 supraclavicular blocks, using a paresthesia technique. Eighty percent of their patients were followed up; three cases of serious nerve injury were apparent, but on further investigation they all were found to have resulted from coincidental (surgical) lesions. Dental surgeons have been advised for some years to use long bevelled needles [2].

We cannot be so certain as Baranowski and Buist of detecting nerve fascicle penetration. During microneurography in awake humans [3] when paraesthesiae were elicited, in only a minority of cases was a fascicle impaled (as indicated by a neurographic recording). To be certain that fascicular penetration had occurred, it was necessary to elicit sensations by electrical stimulation at currents of less than 40 µA. The nerve stimulators used in regional anaesthesia are not capable of operating reliably in this range, and are able merely to detect proximity to a nerve trunk [4].

The optimum bevel configuration of needles used in human regional anaesthesia remains to be ascertained.

Sir—It is with great interest that we read the editorial [1] on peripheral nerve damage and we wish to relate to our experience in the prevention of neuropathies after peripheral nerve block. Although a review article [2] suggested that the incidence of neuropathies is small, very serious damage has been reported [3, 4].

We believe that seeking paraesthesiae increases the risk of this type of complication [4, 5], therefore, for the past 2 years, we have been using a nerve stimulator (Pajuncka 861 Germany) which is thought to reduce nerve trauma [6]. Frequency of stimulation is 1 Hz and the intensity generally 0.25 mA for the upper limb and 0.5 mA for the lower limb. We perform regional blocks in conscious, unsedated patients who are not under general anaesthesia. We prefer insulated, short-bevel needles (Stimuplex—Kanüle A, Braun, Germany) rather than pin-point needles, as they enable us better to discern the clearing of the neurovascular sheath in upper limb blocks and in addition, the local anaesthetic is delivered directly onto the nerve. We connect the needle directly to a catheter as recommended by Winnie [7]. The catheter is never filled during the period of seeking the nerve, as we believe that the dispersion of even a small quantity of local anaesthetic near the needle may earth the current, thus inhibiting muscular contractions; above all, it would be dangerous to mask puncture of a nerve [3]. We always prefer to make a single injection of a large volume (30–60 ml) of local anaesthetic (isotonic salt solution, plain 1% lignocaine and 0.5% bupivacaine in a ratio 1:1:1, together, with an opioid (fentanyl or buprenorphine)). I.v. sedation may be administered when the block is complete. For axillary blocks, we prefer to use a single large injection rather than using a "trunk-by-trunk" seeking approach. When this option is chosen, it may be preferable to begin with the most posterior nerves [8].

Since we started following this procedure, we have performed 230 axillary blocks and 80 lower limb blocks with a rate of immediate success of about 86%. We have observed no nerve damage or postanaesthetic dysaesthesiae in the patients. In conclusion, we prefer the axiom "no paresthesia no dysaesthesia" to the outmoded "no paresthesia no anaesthesia" of Moore.

STATISTICAL ASSESSMENT OF TWO METHODS OF CLINICAL MEASUREMENT

Sir,—I read with interest the article by Berridge describing the influence of cardiac output on the correlation between mixed venous and central venous oxygen saturation [1], but was disappointed by its analysis and conclusions. The finding that mixed venous and central venous oxygen saturations measured simultaneously are highly correlated whether cardiac output is small, medium or large does not justify the conclusion that central venous oxygen saturation is a useful estimate of mixed venous oxygen saturation. Such a conclusion requires the appropriate analysis—the Bland–Altman technique for assessing the degree of agreement between two methods of clinical measurement [2]. The deficiencies of the calculation of correlation coefficients in this context are well recognized. A correlation coefficient measures the strength of a relationship between two variables, not the agreement between them. Only agreement between the actual numerical values obtained by the two methods is clinically relevant. If measurements using two different methods are clustered closely around any line (not necessarily the line of equality), they give a high correlation coefficient whether they are in agreement or not. In the circumstances of this study, it is inconceivable that there would not be a strong relationship between mixed venous and central venous oxygen saturations regardless of cardiac output.

In contrast, the Bland–Altman technique directly examines the differences between measurements made using two methods. The first step is to plot the difference between measurements made using two methods against their mean. In this study, the difference between simultaneous mixed venous and central venous oxygen saturations would be plotted against their mean. If there is good agreement between methods of measurement, the mean difference is close to zero with little variability. This graphical technique clearly displays bias (when the mean difference is other than zero). It also shows if differences vary in a systematic way over the range of measurement—that is, if agreement between methods is poorer at larger or smaller values. Further analysis can give limits of agreement, which are the mean difference ± 2 standard deviations of the differences, and their 95% confidence intervals. It is disappointing that the article gave no graphical information; however, the figures in table I do indicate a bias between the two methods of measurement with central venous oxygen saturation consistently greater than mixed venous saturation. Data in table I also suggest that the variability around this bias became wider as cardiac output and mixed venous oxygen saturation decreased. These are precisely the type of insights that a Bland–Altman plot provides and that correlation coefficients can never convey.

The appropriate analysis of the data presented would therefore have been Bland–Altman analysis of the measurements to give a bias and limits of agreement for each of the three groups in the study. Appropriate plots would have indicated clearly if the difference between mixed venous and central venous saturation increased as cardiac output and venous saturation decreased. The extent of acceptable limits of agreement is a clinical decision (usually specified before the study begins) and so it is inappropriate to apply a statistical test to the different limits of agreement for the three groups.

The Bland–Altman technique was first proposed in 1983 [3] and its merits have since been well demonstrated [4, 5]; clear examples of its use have appeared in the standard British anaesthetic journals [6, 7]. It is therefore disappointing to see published a study in which poor choice of statistical technique has fostered inappropriate and misleading conclusions.

Sir,—Thank you for the opportunity to reply. Dr Runcie has correctly stated that correlation is a poor method of determining how closely two methods of measurement agree and I thank him for pointing out this oversight. I therefore provide him with the data he requested, in figure 1. As can be seen, there is a bias, with the central venous sample overestimating the mixed venous. The 95% limits of agreement of that bias are: −0.46 to 7.46% in the small cardiac index group, −3.02 to 9.22% in the medium cardiac index group, −1.59 to 7.19% in the large cardiac index group and −2.6 to 8.8% overall. These limits of agreement are not significantly different between the three groups, suggesting that central venous oxygen saturation as an estimate of mixed venous oxygen saturation is not unduly influenced by cardiac output. It is up to the individual to decide if these limits militate against using central venous oxygen saturation as an estimate of mixed venous oxygen saturation. The reliability of central venous samples to pick up changes in mixed venous oxygen saturation is currently being investigated.

Leeds

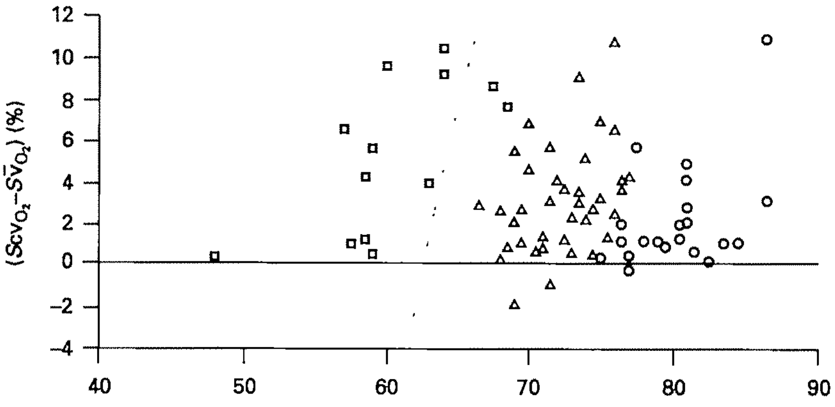

FIG. 1. Bland–Altman plot of difference between central venous and mixed venous oxygen saturation ($Scv_{O_2}-S\bar{v}_{O_2}$) against the mean of the two saturations (($Scv_{O_2}+S\bar{v}_{O_2}$)/2), with small (□), medium (△) and large (○) cardiac index.

CRICOID PRESSURE AND THE LARYNGEAL MASK AIRWAY

Sir,—We read with interest the paper by Ansermino and Blogg [1] on cricoid pressure and insertion of the laryngeal mask airway (LMA). The authors describe a single-blinded randomized, controlled study in which insertion was successful in only three of 20 patients. We were surprised at these results, which are in direct conflict with those of a previous study [2], and we wish to comment further, particularly on the criteria used to assess successful insertion.

Successful placement of the LMA was determined by the presence of all of the following: resistance to continued advancement, outward movement of the LMA on inflation of the cuff, appearance of condensation in the LMA tubing after attachment to the anaesthetic system and gentle manual ventilation with satisfactory compliance. Although all of the above criteria are consistent with successful LMA insertion, we feel that none is a suitable end-point for assessing successful insertion in a clinical trial. The first two criteria fail to demonstrate the final position of the LMA in the hypopharynx. The presence of condensation is difficult to assess in an opaque tube, and perhaps capnography would have been a more reliable technique. The final criterion is subjective and open to considerable interpretation. Furthermore, the authors fail to mention which criteria were not met in those patients in whom LMA insertion was deemed a failure; this information would be of interest in identifying factors producing the poor results with cricoid pressure obtained in this study.

The prerequisite for determining successful insertion is that the LMA provides a clear, functional airway. This usually is dependent on satisfactory placement in the hypopharynx. The position of the LMA is verified easily using a fibreoptic scope passed to the level of the mask aperture bars, and the view obtained may be scored. There are several methods for evaluating function, both subjective and objective, including observation of thoraco-abdominal movement, spirometry and chest transducers. None of the criteria used in this study is a convincing measure of adequate function and they are therefore of questionable value in assessing successful LMA placement, even when taken together.

The role of the LMA in failed intubation requires further elucidation. A recent postmortem study has indicated that, when *in situ*, the LMA does not compromise cricoid pressure [3]. The decision as to whether to use the face mask or the LMA as the first choice alternative to intubation is guided better by studies comparing the two techniques under similar conditions. Ansermino and Blogg suggest that the face mask should be the first choice and the LMA used only as an alternative to cricothyrotomy. We believe that there may be situations in which it would be appropriate for an experienced user to regard the LMA as the best alternative, particularly where difficulty may be anticipated with a face mask. We would also suggest that LMA insertion should be attempted before cricothyrotomy, which carries its own inherent risks.

In an attempt to resolve some of these problems, we are conducting a blinded, randomized, controlled study in which the LMA is inserted in a simulated failed intubation. Successful insertion is judged by function and fibreoptic positioning. The results so far indicate that, whilst insertion is slightly more difficult with cricoid pressure applied, it is successful in 80–90% of patients at the first attempt.

Based on these preliminary findings, and the results of a previous unblinded study in which insertion was successful in 34 of 40 of patients with cricoid pressure applied [2], we feel it is premature to suggest that cricoid pressure should be routinely released, albeit transiently, to allow placement of the LMA in a patient at risk of aspiration.

J. Brimacombe
A. Berry
Royal Perth Hospital
Perth, Australia

1. Ansermino JM, Blogg CE. Cricoid pressure may prevent insertion of the laryngeal mask airway. *British Journal of Anaesthesia* 1992; **69**: 465–467.
2. Brimacombe J. Cricoid pressure and the laryngeal mask airway. *Anaesthesia* 1991; **46**: 986–987.
3. Strang TI. Does the laryngeal mask airway compromise cricoid pressure? *Anaesthesia* 1992; **47**: 829–831.

Sir,—In their paper on cricoid pressure and the laryngeal mask airway [1], Drs Ansermino and Blogg reported that successful insertion was achieved in only three of 20 patients in whom cricoid pressure was applied, compared with 19 of 22 without cricoid pressure. In their discussion of these results they refer to our study [2] as if it had aims (and indeed results) similar to theirs. This is incorrect. Our study assessed ability to intubate blindly through the laryngeal mask. The effects of cricoid pressure were assessed in 50 patients, in all of whom we were able to insert the laryngeal mask satisfactorily (on the simple clinical criterion of easy manual ventilation) during application of cricoid pressure. Our relative lack of success was only in the area of intubation. Thus our results are totally in accord with those of Brimacombe [3], not in contrast as stated by Ansermino and Blogg.

The authors suggested that the lack of skill in insertion of the airway is unlikely to have been a factor in their low success rate with cricoid pressure. They do not comment on their success rate with simulated cricoid pressure (16 of 22 at first attempt, a further three at second attempt, whilst three required removal of the screen). This "success" rate hardly accords with the statement that one of the authors has achieved 648 successful insertions in 10 months (unless he also had 243 failures). We think it far more likely that their experimental design, whilst commendably blind, produced significantly abnormal conditions and that this accounts for the difference between their failure rate (90%, $n = 20$) and that of ourselves and Brimacombe combined (3%, $n = 90$).

We disagree with the authors' conclusions on the utility of the laryngeal mask in patients for whom cricoid pressure is indicated. Our view is supported by the excellent study of Strang [4] which demonstrated that the presence of the laryngeal mask does not compromise the effectiveness of cricoid pressure.

4. Strang TI. Does the laryngeal mask airway compromise cricoid pressure? *Anaesthesia* 1992; **47**: 829–831.

Sir,—Thank you for the opportunity to reply to Dr Heath and Mr Allagain. We could not compare their uncontrolled study directly with our randomized, prospective, comparative and blinded study as their paper [1] did not give details of the successful placement of the laryngeal mask airway (LMA) before they attempted blind intubation, and merely described the success in placing a tracheal tube. In support of our findings that application of cricoid pressure before insertion of the LMA may prevent accurate placement of the LMA, we quoted their failure in 22 of 50 patients to place the tube without release of the cricoid pressure. It is salutary also to record their relative lack of success in this group (44%) in whom cricoid pressure was applied, compared with 90% in those patients who did not have cricoid pressure applied. Despite the unblinded design of their studies, such a marked difference ($P < 0.005$, χ^2 3.95) surely supports our view that cricoid pressure interferes with the placement of the LMA, as that was the only methodological difference between their groups. Indeed, Heath and Allagain themselves state that "momentary relaxation of cricoid pressure during placement of the mask and again during the intubation manoeuvre will provide the best compromise between protection against regurgitation during the procedure and rapid successful intubation".

If our success rate in placing an LMA should be compared with the combination of their's [1] and that from another continent carried out in a different manner [2], then it will be noted that in *all* of our 42 patients the LMA was placed successfully whereas, in the combined series, in 28 of 90 patients intubation could not be achieved whilst cricoid pressure was applied. Further, in three patients the LMA could not be positioned satisfactorily within 1 min, resulting in abandonment of the attempted intubation.

The failure to pass the tube or the LMA successfully may be the result of several factors. Heath and Allagain suggest themselves that cricoid pressure encourages "downfolding" of the epiglottis sufficient to allow unsatisfactory intubation. Difficulties in accurately judging placement of the LMA, or tube, are illustrated further by their suggestion that intubation could be unsatisfactory "despite clear evidence of the tube being placed within the respiratory pathway". Practised users of the LMA will appreciate that simply relying upon ability to inflate the lungs via a LMA is no guarantee of its accurate placement, as the LMA may achieve an air-tight seal despite sitting above the larynx—hence our reliance on a battery of tests to confirm the placement.

It should be noted also that the presence of the screen in our blinded series did not hinder placement of the LMA. The screen was removed before successful placement in three of our patients because observation of the patient's clinical condition was obscured in two and its presence impeded use of a laryngoscope in the third.

Heath and Allagain further confuse the problem by quoting the study by Strang [3], in which the efficacy of the LMA was tested in cadavers in whom the LMA had been inserted *before* application of cricoid pressure, and the ability to inflate the lungs was not reported. Our experience of studying the use of the LMA in cadavers leads us further to believe that the anatomical differences reduce the applicability of the information obtained.

We stand by our conclusion that cricoid pressure may prevent accurate placement of the LMA and, if there is significant risk of regurgitation, it may be better if a tracheal tube cannot be passed, to maintain cricoid pressure rather than to release it in those patients in whom accurate placement may be prevented.

LAPAROSCOPIC *VS* OPEN CHOLECYSTECTOMY

Sir,—We read with interest the paper by Joris and colleagues [1]. It is widely reported that patient recovery is more rapid after laparoscopic than after open cholecystectomy. The biochemical basis of this remains to be determined. This study adds further to the weight of evidence demonstrating a reduction in the acute phase response after laparoscopic cholecystectomy. Mealy and colleagues [2] also documented significantly smaller C-reactive protein concentrations after laparoscopic compared with open cholecystectomy.

We have conducted a similar study in 25 patients undergoing elective cholecystectomy [3]. Mean interleukin-6 concentrations peaked at 4 h after surgery (57.2 and 99.3 pg ml^{-1} in the laparoscopic and open groups, respectively ($P < 0.01$)). Mean C-reactive protein concentrations at 24 h were 17 and 49 mg litre^{-1} and at 48 h after operation were 28 and 70 mg litre^{-1} in the laparoscopic and open groups, respectively ($P < 0.01$).

We also assessed recovery of our patients in the 48 h after operation, using subjective fatigue scores and voluntary hand grip strength. The mean fatigue scores of both groups at 24 h after surgery were significantly greater than the values before operation ($P < 0.05$). The mean fatigue score of the laparoscopic patients at 48 h had returned to the preoperative value, whilst that of the open cholecystectomy patients remained significantly increased and was significantly greater than that of the laparoscopic group ($P < 0.05$). Voluntary hand grip strength was reduced significantly only after open cholecystectomy, and only at 24 h after operation ($P < 0.05$). A similar pattern of fatigue and impairment of voluntary muscle strength in the patients studied by Joris and colleagues may have contributed to the impairment of pulmonary function which they identified.

We extended our study of patient recovery to include the first 1 month after discharge from hospital. Patients were requested to complete questionnaires, detailing fatigue sensation, pain and actual daily activities, at 1-week intervals for 4 weeks. Preliminary findings would suggest that laparoscopic patients remain pain free in the 2–3 weeks after discharge. However, during this period there appears to be a trend for their mean fatigue score to increase to greater than that recorded before operation. Thus it is possible that a cohort of patients undergoing laparoscopic cholecystectomy may develop a fatigue syndrome during the postoperative period, similar to that which may occur after laparotomy [4] and which has, as yet, not been recognized.

It is reasonable to speculate that the reduction in the acute phase response, possibly caused by reduced tissue trauma [5], is linked to early recovery after laparoscopic cholecystectomy. Christensen and Kehlet [6], have shown that postoperative fatigue is not predictable from preoperative nutritional status and that it does not correlate with postoperative changes in haemoglobin, albumin, electrolytes or various minerals. The role of cytokine activity in postoperative recovery and fatigue has not been investigated specifically, although evidence now available suggests that this is worth pursuing. However, this will necessitate controlled studies continuing for several weeks into the postoperative period.

COMBINED CAFFEINE–HALOTHANE TEST FOR MALIGNANT HYPERTHERMIA

Sir,—The article by Halsall and Hopkins [1] examined the value of the combined caffeine–halothane test for malignant hyperthermia (MH) and in the process questioned many issues surrounding MH diagnostic contracture testing. I manage an MH diagnostic centre that has used the combined caffeine–halothane contracture test involving nearly 400 patients. We initially referred to positive responders as "K" phenotypes [2] because Kalow (with Britt and Chan) originally described the population [3]. I continue to use this controversial test because I believe that MH is genetically heterogenous in humans; that, individually, halothane or caffeine tests may not identify all MH-susceptible probands; and that generation of false positives is more desirable than production of a population of false negatives—that is, all susceptible relatives of all falsely diagnosed MH-susceptible probands.

There are several disturbing aspects of the report by Ellis' group that should be questioned. First, it must be pointed out that, in contrast to the North American MH diagnostic procedure [4, 5], the European procedure has not been scrutinized analytically among and within diagnostic centres and there are no scientific data available to assess the sensitivity or specificity of these tests. Only two fascicles are used for each of the standard tests, and only one fascicle was used for the caffeine–halothane test. Would the diagnostic outcome be different if three fascicles instead of two were used in the European procedure (as per the North American procedure)? Certainly, the use of only one fascicle per patient for the caffeine–halothane test is inadequate for the hypothesis testing attempted in this study. The presentation of the data in table I is biased and misleading, as is discussion of the issues within the text. There is no scientific basis of proof that the K responders in the MHN group are truly MH negative. From the data presented in table I, it is inferred that the combined caffeine–halothane test results in a false negative rate of 45 %. Also, the authors stated that "the CHCT can produce both false positive and false negative results... and is potentially dangerous." Preceding these statements, they observed that exposure to 1 % halothane produced large contractures and that, following this, the contracture response to caffeine did not exceed 1 g. The authors declared this as an MH-negative response for the CHCT test. They stated, "It is questionable if the CHCT should be classed as negative in this situation," but then present the data and discuss it in a very biased manner. To skew the data by interpreting these responses as negative is scientifically unsound and unjustified.

I believe that the time has come for all who deal with this disease to realize that it is a complex process, predisposed by mutations that can differ from one family to another [6] and by environmental factors that we do not yet understand. If we believe that existing diagnostic tests are truly sensitive and specific, then we deceive ourselves. What if we were to limit diagnostic tests to only the *in vitro* contracture responses of muscle from patients who have developed the "malignant syndrome"? We would exclude some families who are also predisposed, perhaps less profoundly so, but still to an extent that could be life-threatening. An open-minded, objective evaluation of malignant hyperthermia must be maintained in order to advance our knowledge and understanding of this disease.

6. Levitt RC. Prospects for the diagnosis of malignant hyperthermia susceptibility using molecular genetic approaches. *Anesthesiology* 1992; **76**: 1039–1048.

Sir,—We agree with many of the points raised in Dr Nelson's letter. There is now no doubt that MH is heterogeneic. Within the European population, there are more families who do not show linkage with the RYR gene on chromosome 19 than do. Also, the so-called "pig-mutation" is not a feature of human MH.

What is surprising is the continued value of the halothane (and the caffeine) contracture tests, even though in different families different genes are responsible for the transmission of MH susceptibility (MHS).

With the halothane-caffeine combined contracture test (CHCT), abnormal results are obtained in more than 10 % of the population. Clearly, therefore, the combined test cannot be specifically predicting MHS, which we know to be a comparatively uncommon state, about 1 in 8000 of the population. If human MH were a recessive characteristic (as it appears to be in the pig) an incidence of 10 % might be reasonable. However, within the families, the distribution of MHS individuals shows the MH gene clearly to be dominant. Thus there seems to be no rationale for the caffeine–halothane combined test in MH screening.

It is difficult to see how to display our data, except as in table I. It is apparent that there is controversy about the interpretation of the results of the CHCT. We followed that described by Melton and co-workers [1], who described the test as positive if 1 g of tension was reached after the addition of caffeine. If an alternative interpretation is taken to be a total of 1 g increase in tension from the predrug tension, the number of normal CHCT results in otherwise MHS patients may decrease. The North American MH group procedure has not attempted to define the limits of the CHCT [2]. In the light of this difference in interpretation, we have reassessed the results and find that the negative CHCT was reduced from 10 to four in MHS patients and from six to five in MHE(h) patients. This alteration in the interpretation of the results does not affect the MHN group.

The validity of the European Group's procedure was presented in our discussion, although formal "analytical scrutiny" has not been performed among all the European diagnostic centres. However, all the larger centres have control data and the diagnostic procedures in Leeds have stood the test of more than 20 years and more than 2500 biopsies. Perhaps that is more valid than analytical scrutiny of a few results.

In order to substantiate a different type of MH-susceptible patient characterized by the K-type, a clear demonstration of its inheritance through the family is needed if Dr Nelson's view is to retain any credibility.

SPIN RESONANCE SPECTROSCOPY TO DETECT MALIGNANT HYPERTHERMIA SUSCEPTIBILITY

Sir,—We note the results reported in the paper by Halsall, Ellis and Knowles [1] and those reported in another recent study of malignant hyperthermia (MH) [2]. Both studies attempted to reproduce the results of an MH study of Ohnishi and colleagues [3]. The first concluded, from a study of 10 MH-susceptible (MHS) and nine MH-normal (MHN) patients, that there was no significant difference in the fluidity of red blood cell membranes from the two groups. The second concluded, from a study of six MHS and six MHN volunteers, that a significant difference ($P < 0.001$) existed between their two groups both with and without fluidization using halothane. Both studies measured the rotational correlation time (τ_r) of the 16-deoxylstearic acid spin label at 37 °C using 9-GHz electron paramagnetic resonance (EPR) spectroscopy. There appear to be several important factors that should be examined.

The sample preparation procedures were similar but not identical. Initially, Cooper and colleagues [2] attempted to produce spin-labelled erythrocyte samples using the method of Ohnishi and colleagues [3]. However, EPR spectra were not observed, so they developed a revised method [2]. It can be concluded that this method of Ohnishi and colleagues [3] resulted in spin-label:lipid ratios which were sufficient to induce significant erythrocyte (red blood cell) membrane perturbations. This conclusion is in agreement with the observation that the τ_r values reported [3] are inconsistent with the hypothesis that MHS erythrocyte membranes should be more fluidized than MHN membranes. The procedure of Cooper and colleagues [2] led to values that were consistent with this hypothesis, although the differences were not significant; they ascribed this to the fact that it is very difficult to fluidize samples consistently and accurately using halothane. They estimated that their method resulted in spin-label:lipid ratios that did not exceed 1:100, so the membranes were not perturbed significantly, in agreement with a electron microscopic study [4]. It is suggested that use of the method of Ohnishi and colleagues by Halsall and colleagues [1] also resulted in significant membrane perturbation.

No information concerning the repeatibility of EPR spectral analysis measurements was given by Halsall and colleagues [1] or Cooper and colleagues [2]. The latter used a digital data

TABLE I. *Mean* (SEM) *rotational correlation times* (τ_r) *for the MHS and MHN sample groups with fluidization produced by various concentrations of halothane* [1, 2] *and benzyl alcohol* [2]

acquisition system which resulted in 1200 data points over the 10-mT magnetic field sweep width. The precision for individual measurements could be improved from approximately 0.5% to approximately 0.1% by the introduction of the software program which was developed. This precision was determined by repeating the analysis several times and by using different analysts. This experience leads to the conclusion that the precision achieved by Halsall's group [1] using a set-square and calipers to measure a spectrum could not exceed 0.5%, and probably 1% is more realistic. Moreover, the signal-to-noise ratio achieved by Cooper's group [2] was approximately 300:1, whereas it was approximately 100:1 Halsall's group [1]. This also contributed to the precision achieved by the former, who used a blind sample labelling procedure to remove bias concerning the sample group membership. Halsall and colleagues [1] reported that the τ_r values were very sensitive to small changes in the central line width (W_0), whereas Cooper and colleagues [2] found that W_0 was essentially independent of the degree of fluidization.

Both studies [1, 2] assessed the statistical significance of the mean τ_r values for the MHS and MHN sample groups using the Mann–Whitney *U* test, and agree that no significant differences were attributable to halothane or benzyl alcohol, contrary to the conclusion of Ohnishi and colleagues [3]. However, Cooper and colleagues [2] found that the differences between the mean τ_r values for the MHS and MHN sample groups were significant for all concentrations of each of the two membrane fluidizing agents. It is evident from the data of Halsall and colleagues [1] that there was no significant difference between the MHS and MHN sample groups for both halothane concentrations within the SEM values for each group.

Table I summarizes the mean (SEM) values of the rotational correlation times (τ_r) for the MHS and MHN sample groups with halothane 0, 0.3, 1.0 and 3.0 mmol litre^{-1} [1, 2] and with benzyl alcohol 0, 25 and 50 mmol litre^{-1} [2]. The SEM values of Halsall and colleagues [1] are more than six times those of Cooper and colleagues [2], in agreement with the measurement precision estimates discussed above.

It is concluded that erythrocyte membranes are a good proxy for skeletal muscle membranes. This suggests that MH may be a symptom of a generalized membrane defect, contrary to general belief and other evidence [5].

Sir,—Thank you for the opportunity to reply to the letter by Buckmaster and colleagues, which we found difficult to follow. The crux of the matter is that, whereas our studies indicate no difference within the limits of error between normal and MH-susceptible patients for the fluidity of erythrocyte membranes, the data of Cooper and colleagues [1] indicate a small but significant difference. Buckmaster and colleagues criticize our work with respect to sample preparation, electron paramagnetic resonance (EPR) spectral analysis and statistical analysis of the data.

Taking these points in turn, our sample preparation attempted to reproduce that used by Ohnishi and colleagues [2]. Unlike Cooper and colleagues [1], we had no difficulty obtaining spin labelling of erythrocyte membranes by this procedure. Our spin labels (16-deoxylstearic acid 1 mol/100 mol membrane lipid) are unlikely to have induced any membrane perturbation [3].

Our EPR data collection procedure is closely similar to that of Cooper and colleagues [1]; both involve digital acquisition of 1200 data points over a 100-mT magnetic field sweep. Determination of the rotational correlation time from the spectra both in our studies and in those of Cooper is based on the method of Keith, Bulfield and Snipes [4].

We analysed the spectra manually, whereas Cooper and colleagues [1] determined their correlation time using computer analysis of the acquired digital data. The latter is clearly superior. Both the Leeds and the Calgary studies used a blind sample procedure to remove bias and the statistical analysis procedures were the same.

On balance, the most likely explanation for the difference in results obtained in Leeds and Calgary lies in the determination of the rotational correlation time from the EPR data. We will use the amended EPR analysis procedure suggested by Cooper and colleagues [1] to re-examine this matter. It is important that it be resolved, because of the implications of a generalized membrane defect in MH.

THE AIRWAY DECIDES THE ANAESTHETIC APPROACH BEFORE TRACHEAL INTUBATION

Sir,—The review by Cobley and Vaughan [1] dealt with difficult intubation, rather than difficult airways, and therefore seemed incorrectly titled. "Difficult airway" and "difficult intubation" do not always, or necessarily, occur together and they are not synonymous and interchangeable [2]. In the absence of pre-existing compromise of the airway, or its control and maintenance, inability to see the glottis with a laryngoscope does not automatically translate to, or equate with, a "difficult airway" being present. In practice, such an association is uncommon.

The tracheal tube is *an* airway, but not *the* airway. Whilst failure to intubate may delay surgery temporarily, failure to maintain the airway, and oxygenation, can cause serious or lethal damage to the patient. Cerebral damage or death are the sequelae, not of "inadequately managed difficult intubation" [1], but of the inadequately managed, or lost, airway. Careful preoperative assessment is the best method of avoiding disaster [1] because it predicts potentially difficult airways rather than because it predicts "difficult" intubations [1]. Signs of the first are amongst those usually used for the second. Some form of anaesthesia is usually required before tracheal intubation. The decision to use i.v., inhalation or awake local anaesthesia is dictated by assessment and difficulty of the airway, as is the anaesthetic approach to the compromised airway [3]. The choice should err on the safe side and will reflect the anticipated ability (or not) to control or retain the airway with a particular approach. The decision on the airway must be made before induction of anaesthesia. Using i.v. induction agents in sleep doses for insertion of a tracheal tube [4] or laryngeal mask [5, 6] when airway control is compromised and uncertain carries considerable risk if the placement of the device proves unsuccessful or difficult.

The value of transtracheal ventilation and of retrograde intubation, especially for the inexperienced, is that they circumvent airway and intubation problems and are possible in the awake patient. Awake intubation is necessitated, not by intubation, but by airway considerations. It seems misused and overused.

Cobley and Vaughan [1] could also have mentioned ketamine and topical anaesthesia in the young [7, 8], nasopharyngeal airways and the possible relevance of the sleep history.

Sir,—We thank you for the opportunity to reply.

Most anaesthetists when faced with "the difficult airway" would, in our experience, try to secure that airway with a tracheal tube. The title of our article was therefore chosen with this broad principle in mind. However, we accept that "difficult intubation" would have been more appropriate.

PAIN RELIEF AFTER ANTERIOR CRUCIATE LIGAMENT REPAIR

Sir,—Dr Joshi and colleagues are to be commended for emphasizing the problem of severe pain after knee surgery and for describing their technique of intra-articular morphine infusion [1]. We agree that both PCA and continuous neuraxial infusions are not ideal in this situation.

However, we would have included local anaesthetic neural block in our list of postoperative analgesic alternatives. Both the sciatic and the femoral nerves can be located reliably and blocked with the aid of a nerve stimulator. The duration of high quality analgesia thus obtained frequently exceeds 24 h.

Perhaps, as we enter the age of "pre-emptive analgesia", lower limb peripheral nerve block will begin to receive the attention it deserves.

Kings Lynn

1. Joshi GP, McCarroll SM, Brady OH, Hurson BJ, Walsh G. Intra-articular morphine for pain relief after anterior cruciate ligament repair. *British Journal of Anaesthesia* 1993; **70**: 87–88.

Sir,—Thank you for the opportunity to reply to the letter from Drs Carroll and Allen. The aim of our study was a clinical evaluation of the effectiveness of intra-articular morphine in relieving acute pain in the early postoperative period after anterior cruciate ligament (ACL) repair [1]. We agree that the use of peripheral neural block can be considered an alternative method of postoperative analgesia after ACL repair.

Recently, peripheral blocks have attracted attention as there is now substantial evidence that pre-emptive analgesia diminishes postoperative pain and requirements for supplementary analgesics [2, 3]. Continuous lumbar plexus block has been shown to be effective in patients undergoing open knee surgery [4, 5]. However, the placement of a catheter into the perineural space requires skill and experience. It is time-consuming, and may not be agreeable to all patients. It also has the disadvantage of producing motor block which can delay ambulation. Intra-articular injection of morphine is a simple and safe technique which does not require any special skill or equipment.

BOOK REVIEWS

The Oxford Textbook of Clinical Pharmacology and Drug Therapy, 2nd Edn. By D. G. Graham-Smith and J. K. Aronson. Published by Oxford University Press, Oxford. Pp. 756; indexed; illustrated. Price £17.50.

This textbook, written primarily for undergraduates, was first published in 1984. In this new edition, the main change has been the inclusion of a large number of invited contributions from "specialists" on the drug treatment of disease. The book is laid out in four sections comprising the scientific basis of drug therapy, prescribing, the drug treatment of disease and a pharmacopoeia. More than 70% of the book is concerned with the scientific basis of drug therapy and the drug treatment of disease. It is produced as a laminated hardback and should prove sufficiently durable for the majority of students.

The opening section on pharmacological principles is a model of clarity and can be recommended without reservation to all medical students and to those preparing for the Part 2 Anaesthetic Fellowship examinations of the Royal Colleges. The drug treatment of disease is, for the most part, comprehensive and will serve as a useful reference. Unfortunately, a few myths are perpetuated and whereas some of these are simply amusing, others are positively dangerous. It is, of course, a fallacy to believe that, in the treatment of drug overdose, hypoxaemic patients should be given "24% oxygen increasing to 28% oxygen after 30 minutes if the alveolar carbon dioxide tension has not risen". This is nonsense, and simply will not do!

It is also very disappointing that the opportunity was not taken to provide a section dealing with the drug management of chronic pain. It is widely recognized that this common problem receives scant attention in the medical curriculum and this book has failed those who are trying to remedy the situation. The treatment of intractable pain in terminal malignancies is covered in half a page and that of a few other chronic pain syndromes is covered superficially in different chapters.

The chapter on general anaesthesia and local anaesthetics is a worthwhile introduction to the subject.

It is perhaps inevitable, in a book written by clinical pharmacologists, that the emphasis should be on the drug management of what have traditionally been considered medical conditions. For example, inotropic drugs are discussed mostly in terms of their use after myocardial infarction and there is very little mention of their role in the management of trauma or endotoxaemia. Similarly, the use of non-steroidal anti-inflammatory drugs for the treatment of arthritic conditions is covered comprehensively, but there is only the most superficial mention of their role in postoperative pain management. Patient-controlled analgesia systems are ignored.

This new edition has attempted, like its predecessor, to bridge the gap between pharmacology and the clinical management of disease states. In general it has succeeded, but it is not sufficiently comprehensive or authoritative to warrant an unreserved endorsement for topics outside the field of internal medicine.

J. P. H. Fee

Handbook of Percutaneous Central Venous Catheterisation, 2nd Edn. Edited by M. Rosen, P. Latto and S. Ng. Published by W. B. Saunders Co., Ltd, London, Philadelphia, Toronto, Sydney, Tokyo. Pp. 249; indexed; illustrated. Price £19.95.

This is the second edition of a book which was very well received when it appeared 9 years ago. Its format is very close to the original. The first part of the book describes the indications for the insertion of catheters. Each separate section gives an outline description of a different method. The dangers and complications are mentioned and in most cases the frequency is given at which such complications occurred in a published series.

Each section is accompanied by a comprehensive list of references. Many of these are not of recent date, but this may just indicate that there is nothing new to say about the indications for, and complications of, i.v. catheter placement.

Part 2 of the book is devoted to cannulation and catheterization in infants. This is a particularly useful section.

The illustrations form a major part of the book. The line diagrams are much better than the photographs and some of the x-rays are of limited value, as they are used simply as backgrounds upon which lines are drawn to indicate incorrect and correct position of catheters.

Inevitably, there are some techniques described which are such that one can only be tempted to think, why was this method attempted? The Editors give clear preference to some of the techniques, based upon their own experience.

Although I do not believe that a complete tyro could become competent after reading this book, there are some very useful hints in it which can be read with benefit by even the most experienced.

In summary, I believe this book has become the Bible of the cannulist and will continue to be as popular.

J. C. Stoddart

Electrical Trauma: the Pathophysiology, Manifestations and Clinical Management. Edited by R. C. Lee, E. G. Cravalho and J. F. Burke. Published by Cambridge University Press, Cambridge, New York. Pp. 440, indexed; illustrated. Price £65.00.

Three American professors (two surgeons and a medical engineer) have led a team of 31 contributors to produce a book the stated aim of which is to be a comprehensive review of the pathophysiology and clinical manifestations of electrical trauma. They have succeeded admirably, with the technical chapters in the latter half of this book being jewels of considerable clarity.

The book is subdivided into four sections: the introductory three chapters in Part I provide a historical review which includes a useful résumé of basic electrical physics, a summary from the national electrical supply company of France of the investigation of electrical accidents over 40 years, and an excellent chapter presenting an overview of the pathophysiology and clinical management of electrical injury. Part II offers, from a broad range of United States Burns Units, nearly 100 pages on how to look after these patients who comprise a significant proportion (5%) of admissions. The book then turns, in parts III and IV, to the cellular aspects of these injuries, entitled "Tissue responses" and "Biophysical mechanisms of cellular injury". I cannot comment on the merits of the physics contained in these latter 20 chapters, but it is sufficient to say that each undoubtedly gives an up-to-date review in its respective field.

From the viewpoint of a burns surgeon, there are many welcome teaching points included within this book: the importance of "hidden damage" between the entrance and exit wounds which is often missed in electrical burns extending between the upper and lower limbs; the value of the "empirical" fasciotomy in patients with high-voltage injuries of the upper limb (and not just the hand) before signs of compartment syndrome are evident (this is one time when anaesthesia is necessary for a burns fasciotomy, unlike thermal burns); the awareness of the occurrence of skeletal fractures and joint dislocations as a result of tetanic contractions. There are many more.

As one might expect from a book with an almost entirely transatlantic list of contributors, there are details with which I could disagree. In the United Kingdom we do not routinely use allografts to cover decompressed viable muscle during serial debridements, relying often on antiseptic dressings, and I would use systemic antibiotics rather than a topical antimicrobial as prophylaxis against *Clostridium* infection. There are also differences in our National Grid which negate many of the figures given for transmission and distribution voltages.

These points, however, do not detract from the value of this book. I can confirm the publisher's claim that it is suitable for clinicians in trauma surgery, accident medicine, plastic surgery, intensive care and burns units, and recommend it wholeheartedly as a reference book for the library in any of these departments.

EDITORIAL

IVOX

IVOX (Cardiopulmonics, Salt Lake City) is the registered acronym for an i.v. oxygenator. The device is undergoing Phase II evaluation of efficacy as part of the management of acute respiratory failure (ARF) in designated centres in Europe and the U.S.A. IVOX acts as a "lung assist" using hollow fibres for intracorporeal gas exchange and is designed to lie freely within the lumen of the superior and inferior venae cavae.

The drive to develop IVOX has been stimulated by the progressive limitation of the lungs to effect gas exchange in some cases of advanced lung injury and adult respiratory distress syndrome (ARDS). Mechanical, positive pressure or high frequency ventilation techniques are the mainstays of ventilatory support in acute respiratory failure. The pathophysiology of advanced lung injuries with increased microvascular permeability and disruption of alveolar architecture leads to a loss of area for gas exchange. In addition, there is evidence that large tidal volumes and positive pressure applied to the airways contribute to this pathology by increasing alveolar oedema and capillary rupture [1, 2].

The initial search for alternative methods of gas exchange led to the development of extracorporeal membrane oxygenation devices (ECMO). However, with these devices it is necessary to use large extracorporeal blood flows and full systemic anticoagulation. In addition, ECMO requires the continuous presence of perfusionist expertise and the technique is therefore limited to specialist referral centres and for short periods of operation only. More recently, however, advances in the technology of hollow fibres and gas exchange membranes have made artificial intracorporeal oxygen transfer feasible. Mortensen [3] developed these techniques and commenced clinical studies of the safety of IVOX in 1989. These early investigations showed no IVOX-related complications in 20 patients.

Ideally, such a device should comprise a hollow fibre oxygenator, capable of being inserted through a small peripheral venotomy so as to contribute significantly to gas exchange in the venous system. It should not induce thromboembolism or intimal damage and not necessitate full systemic anticoagulation. In addition, it should not impair caval blood flow. Most of these criteria are met by the IVOX device currently available.

The basic functional component is the hollow fibre. Each fibre is a polypropylene former, 35–45 cm in length, depending on the size selected; sizes range from French-gauge 7 to French-gauge 10, related to the transverse diameter in millimetres when the device is furled. An IVOX houses around 1000 of these fibres, each with an internal diameter of 190 μm and a wall thickness of 35 μm. Gas exchange occurs across the 1-μm outer layer around each fibre. This consists of cross-linked dimethyl siloxane overlying the numerous 0.3-μm diameter pores in the hollow fibre. The membrane is selectively permeable to gases, but not to liquids. Each fibre is crimped to encourage turbulent flow and further improve gas exchange. Resistance to thrombosis is produced using covalently bonded heparin and a proprietary thromboresistant outer layer. The fibres provide a total gas exchange area of between 0.21 m^2 and 0.52 m^2 for sizes French-gauge 7–10. However, this represents less than 10% of the equivalent gas exchange area in an ECMO circuit. In the adult, the area of lung surface for gas exchange is of the order of 75 m^2. Oxygen 100% is introduced through the central conduit of a coaxial gas transport tube, entering the fibres at their distal end. Carbon dioxide exchange and oxygen transfer occur as the gases are drawn back along the length of the fibres under a subatmospheric pressure of 300 mm Hg. Waste gases and water vapour are removed via the outer lumen. The negative pressure prevents gas embolization in the event of a fibre fracturing.

The IVOX is inserted as a tightly furled bundle to minimize the size of venotomy required and; it then expands to fill the inferior vena cava (IVC) and part of the superior vena cava. In the current clinical study, 89% of devices have been inserted via the right common femoral and 11% via the right internal jugular veins [personal communication, Cardiopulmonics]. It is important that the largest possible device is used. This has been emphasized by High and colleagues [4] and so it is recommended that the vein is assessed by ultrasound before insertion of the device. An obturator with a haemostatic valve and J-tipped guidewire are introduced and the position checked with an image intensifier. The device is advanced to occupy the entire length of the inferior and superior venae cavae and it is then unfurled to lie loosely within the venous lumen. The widest diameter of the device lies at the level of the intrahepatic IVC. The venotomy is repaired, a bacterial filter is connected to the oxygen inlet and a water trap inserted in the outlet tubing to protect the flow controller. The dose of heparin administered should produce an activated clotting time of no more than 250 s or partial thromboplastin time of 80–90 s. Systemic antibiotic prophylaxis is prudent.

The role of a pulmonary artery catheter (PAC) *in situ*, with the potential difficulties of entanglement, has yet to be fully evaluated. The principal advantage of using a PAC in the presence of an IVOX is that changes in pulmonary blood saturation can give an indication of oxygen delivery when taken in conjunction with cardiac output and haemoglobin. Gas transfer has been measured more accurately using an oxygen–helium mixture and the Haldane correction principle for the input and output gas phases [4]. Carbon dioxide elimination is measured easily using a capnograph and the volume of flow from the vacuum source.

The efficiency of IVOX in terms of gas exchange has been found to vary widely *in vitro*, in animals and in critically ill patients. It is apparent that IVOX can perform only as a lung *assist* device because its oxygen transfer capability is considerably less than basal requirements. The greater rates described are of the order of 140 ml min^{-1} [5], with comparable carbon dioxide removal.

The factors limiting gas transfer may not all be related to the constraints of hollow fibre membrane technology. Because 80 % of the IVOX length is positioned in the inferior vena cava, gas exchange is influenced by splanchnic flow. This may be decreased in ARDS, thereby reducing the efficiency of oxygenation [5]. There are patients whose gas exchange requirements cannot be assisted with IVOX, particularly if they have narrow veins, and it has been suggested [4] that the inability to use a French-gauge 9 or 10 device is a contraindication to IVOX therapy, as gas transfer is always inadequate. Although it is vital to insert the largest possible device, there is a risk of impeding the caval lumen, diverting venous return to the azygos and collateral systems and bypassing the oxygenator.

It has been suggested therefore, that the role of IVOX is to assist gas transfer in patients receiving maximal mechanical ventilation and who have shunt fractions less than 35 % [5]. ECMO would be an option for greater respiratory requirements. Other applications include the support of any potentially reversible ARF and to protect suture lines and minimize air leaks. It is predictable that it will be used for respiratory support before lung transplantation and for some patients requiring ventilatory support. Absolute contraindications are the inability to use anticoagulants safely, persistence of a low cardiac output or identification of bacteraemia or thrombus in the peripheral veins.

The future role of IVOX depends on hollow fibre membrane development and on refinements of technique such as placement of devices to improve oxygenation in mixed venous blood in the superior cava and even the pulmonary artery itself.

The outcome of current multicentre trials is awaited with interest. There will inevitably be problems in matching controls as in ECMO studies. However, the preliminary data (150 implants to date) suggest that the technique requires little more expertise than, for example, continuous flow renal support. It has the advantage of a longer duration of operation than ECMO: the mean duration of use in the current studies is 5.2 days, with a maximum of 29 days [personal communication]. Outcome data are not available yet, but preliminary results suggest early improvements in gas exchange and a reduction in the intensity of ventilator support. The technique may prove to be useful in maintaining life whilst lung injuries resolve, by helping to limit any detrimental effects of long-term mechanical ventilation.

COMPONENTS OF THE INSPIRATORY–ARTERIAL ISOFLURANE PARTIAL PRESSURE DIFFERENCE

M. J. LANDON, A. M. MATSON, B. D. ROYSTON, A. M. HEWLETT, D. C. WHITE AND J. F. NUNN

SUMMARY

We have measured the partial pressure of isoflurane simultaneously in inspired gas (PI_{iso}), end-expired gas (PE'_{iso}), mixed-expired gas ($P\bar{E}_{iso}$), arterial (Pa_{iso}) and mixed venous blood ($P\bar{v}_{iso}$) in six patients (aged 57–79 yr) anaesthetized with nitrous oxide, oxygen and isoflurane before surgery and after PE'_{iso} had been stable for at least 15 min. We related these changes to the various indices of pulmonary maldistribution to determine if they were sufficient to explain reported differences between PE'_{iso} and Pa_{iso}. Alveolar deadspace dilution of end-expired gas was calculated for carbon dioxide and this dilution factor used to calculate the "ideal" alveolar Piso (PA_{iso}) from the observed inspired and end-expired concentrations. Shunt fraction was measured for oxygen and then used to calculate the partial pressure of isoflurane in the pulmonary end-capillary blood (Pc'_{iso}) from the partial pressure in arterial and mixed venous blood. Mean (SE) values were: PI_{iso} 0.69 (0.05) kPa; PE'_{iso} 0.52 (0.04) kPa; PA_{iso} 0.50 (0.04) kPa; Pc'_{iso} 0.38 (0.04) kPa; Pa_{iso} 0.35 (0.03) kPa and $P\bar{v}_{iso}$ 0.22 (0.02) kPa; Pa_{iso}: PE'_{iso} 0.66 (0.02) kPa. The mean "ideal" alveolar to pulmonary end-capillary Piso difference was 0.12 (0.01) kPa and highly significant ($P < 0.001$). Pa_{iso} was substantially less than PE'_{iso} but, for isoflurane, the difference was reasonably constant (range 0.14–0.22 kPa). The difference was attributable in part to the effects of shunt and deadspace, but also a failure of equilibration of isoflurane between the alveolar gas and pulmonary end-capillary blood. It is likely to be different for other anaesthetics. We conclude that, while PE'_{iso} may adequately reflect Pa_{iso} for isoflurane, it cannot be assumed that the relation between end-expiratory gas and arterial partial pressures is the same for all anaesthetics. (Br. J. Anaesth. 1993; **70**: 605–611)

KEY WORDS

Anaesthetics, volatile: isoflurane. Pharmacokinetics: uptake.

The relation between the end-expired and arterial partial pressures of inhaled anaesthetic agents is important for both theoretical and practical reasons. In formulating the concept of MAC, the assumption is made that "the alveolar partial pressure is transmitted without change to the arterial blood" [1] and anaesthetic machines have been developed in which the administration of the agent is controlled by continuous measurement of the end-expired partial pressure [2]. Cromwell and colleagues [3], in a study on healthy volunteers breathing subanaesthetic concentrations of isoflurane, found no significant end-expiratory to arterial partial pressure difference. However, the recently published studies of Frei and colleagues [4] and Dwyer and colleagues [5] have shown an arterial to end-expiratory partial pressure ratio, after equilibration, ranging from 0.79 to 0.86. This ratio can be explained partly by the effects of venous admixture and alveolar deadspace, which are known to be increased in the anaesthetized patient. However, our own preliminary studies [unpublished] suggested that this explanation was insufficient to account for the whole of the arterial to end-expiratory partial pressure gradient for isoflurane. Eger [1] has suggested that anaesthetics of high molecular weight might fail to achieve uniform mixing within the alveolus, resulting in an "ideal" alveolar–pulmonary end-capillary partial pressure difference. To test this hypothesis, we have measured this difference for isoflurane in a group of patients in whom we simultaneously measured the shunt and physiological deadspace according to the three-compartment model (fig. 1). This enabled us to make an estimate of the likely effect of these factors on the end-expiratory–arterial partial pressure difference for isoflurane. In the course of these measurements, we have determined the mixed venous partial pressure of isoflurane, which has not been reported previously in man.

PATIENTS AND METHODS

With the approval of the Hospital Ethics Committee we studied six patients, aged between 57 and 79 yr, undergoing major elective vascular surgery, in whom placement of an arterial cannula and Swan–Ganz catheter was required for clinical reasons. Patients were premedicated and anaesthetized in a routine manner as dictated by the attending anaesthetist. Thiopentone 3–5 mg kg^{-1} was the induction agent

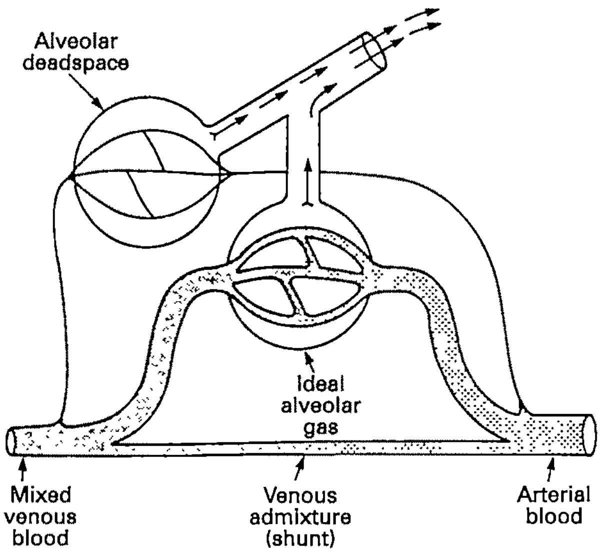

FIG. 1. Three-compartment model used as a basis for calculating ideal alveolar and pulmonary end-capillary partial pressures. (Reprinted with permission from [20].)

used in every case. Paralysis was with vecuronium 0.1 mg kg^{-1} or alcuronium 0.25–0.3 mg kg^{-1}. A cuffed tracheal tube was passed and a leak-proof seal obtained. Anaesthesia was maintained with nitrous oxide, 34–51 % oxygen and isoflurane. After induction, over-pressure of isoflurane (not greater than 2 %) was maintained for not more than 5 min after induction. The inspired concentration was then held constant (range 0.5–0.8 %) until blood samples had been taken (table I). Ventilation was with a Manley MP3 ventilator using a minute volume of approximately 6 litre.

Inspired oxygen percentage was measured continuously in the inspiratory limb of the circuit using a Servomex OA 580 paramagnetic analyser. Inspired and end-expired isoflurane percentages were monitored using a Datex Capnomac (95 % response time 900 ms) and end-expired carbon dioxide percentage was measured using an Ohmeda 5200 CO_2 monitor (95 % response time 360 ms). The sampling lines for isoflurane and carbon dioxide analysis were attached to the catheter mount of the tracheal tube, on the machine side of a Pall BB22–15 breathing system filter and the outputs recorded continuously on a Kipp and Zonen BD9 twin-channel chart recorder. The volume of the filter (approximately 90 ml) was included in the deadspace calculations.

Definitive measurements of end-expired carbon dioxide and inspired and end-expired isoflurane were taken from the chart recorder. A slow ventilatory frequency (approximately 12 b.p.m. with an inspired to expired ratio of 1:4) was deliberately set to allow a plateau for both inspired and expired gas to be recorded. The recorded end-tidal $P\mathrm{CO}_2$ bore the normal relation to the arterial $P\mathrm{CO}_2$ and the recorded inspired Piso agreed closely with a genuine upstream inspired sample measured by gas chromatography. Under these conditions, we are confident that we had a valid end-expiratory sample.

Arterial and mixed venous blood samples were taken after at least 25 min of anaesthesia at a constant inspired isoflurane percentage, with the end-expired isoflurane percentage changing by not more than 0.02 % for at least 15 min. Blood samples for arterial and mixed venous pH, $P\mathrm{O}_2$, $P\mathrm{CO}_2$ and oxygen saturation were obtained anaerobically in duplicate 2-ml, heparinized syringes, using three-way taps to clear the deadspace from both the arterial and pulmonary artery cannulae. Samples were stored on crushed ice for a maximum of 15 min before analysis using an IL 1302 blood-gas machine and an IL 282 Co-oximeter. Oxygen saturation of haemoglobin ($S\mathrm{O}_2$) was derived also from the virtual $P\mathrm{O}_2$ (calculated for 37 °C) using the Severinghaus nomogram [6]. In all cases the calculated saturation agreed with the measured saturation to within 2 % (corrected for carboxyhaemoglobin), the mean difference being 0.1 %. Separate 5-ml blood samples were also obtained to measure arterial and mixed venous haemoglobin concentration and PCV (Coulter Counter model S). Oxygen content of arterial, mixed venous and pulmonary capillary blood was then derived as:

$$[\mathrm{Hb}] \times S\mathrm{O}_2/100 \times 1.31 + 0.0225 \times P\mathrm{O}_2$$

where [Hb] = haemoglobin concentration corrected for carboxyhaemoglobin; $P\mathrm{O}_2$ was at 37 °C; 1.31 = haemoglobin combining factor obtained by Gregory [7]; 0.0225 = solubility coefficient of oxygen in whole blood. The pulmonary end-capillary $P\mathrm{O}_2$ was assumed to equal the alveolar $P\mathrm{O}_2$. This was derived from the Filley equation [8] which allows for nitrous oxide uptake.

Blood samples for measuring isoflurane partial pressure were obtained in gas-tight, heparinized, 2-ml all-glass syringes. Aliquots (0.5 ml) were then injected immediately through a Teflon seal into 2-ml glass vials with loosened screw caps; the caps were tightened immediately after injection. This procedure allowed the blood-gas mixture in the vial to remain at barometric pressure.

During the period of blood sampling, mixed expired gas was collected from the expiratory port of the patient ventilator into a Douglas bag for at least 3 min. After expired gas collection, two 20-ml and two 100-ml samples of inspired gas were obtained from the inspiratory limb of the patient ventilator, and two 20-ml and two 100-ml samples of mixed expired gas from the Douglas bag.

Barometric pressure, room temperature and the patient's tympanic membrane temperature (Mallinckrodt Mon-A-Therm) were noted at the time of sampling and the appropriate corrections made in calculations.

Mixed expired gas samples (100 ml) were analysed in duplicate for oxygen, carbon dioxide and isoflurane by the same monitors used for inspired and end-expired gas analysis. The 20-ml samples of inspired and mixed expired gas were analysed for isoflurane by gas chromatography to cross-check measurements taken from the chart recorder. The mean (SEM) difference was 0.011 (0.009) kPa. The mean value was calculated and used for subsequent calculations.

Isoflurane partial pressures in blood samples were measured as described by Knill and colleagues [9]

using a Pye 104 gas chromatograph (GC) fitted with a 60-µl or 500-µl gas sampling loop and a flame ionization detector. The carrier gas was oxygen-free nitrogen. Oven temperature was 125 °C and detector temperature was 175 °C. The blood-gas samples were equilibrated at 37 °C in a thermostatically controlled chamber by gentle rotation in a vertical plane at 20 r.p.m. for 45 min. A portion of the gas was then flushed into the gas sampling loop of the GC to obtain an isoflurane partial pressure and the remaining gas expelled. The same volume of unequilibrated humidified air was added to the vial and allowed to equilibrate as before. The procedure was repeated four times in total. The natural logarithms of the chromatogram peak heights from each of the four equilibrated gas phases were plotted against the serial number of the equilibration. Assuming that the partition coefficient of isoflurane is independent of absolute tension, these plots should fall on a straight line. The *Y*-intercept is proportional to the partial pressure of isoflurane in the original blood sample. Regression lines for each pair of samples were obtained using the least squares technique and the results averaged. The mean correlation coefficient for the series was −0.9958 (0.0025) and the coefficient of variation between duplicate samples was 2.1%.

To check the accuracy of our isoflurane measurements, 26 normal blood samples were tonometered in a gas flow of known isoflurane partial pressures

(Piso). The partial pressure in the samples was determined as described above. The mean (SE) Piso in the gas phase was 0.241 (0.008) kPa and that in the blood samples 0.243 (0.008) kPa. The difference between paired analyses was not significant (t = 0.76).

Analytical equipment was calibrated before and after each study. The GC was calibrated using the same standard gas mixtures as those used for calibration of the Capnomac and the Ohmeda CO_2 monitor was calibrated against the same standard as that used for blood-gas analysis. The Servomex OA 580 was calibrated with oxygen-free nitrogen and room air. The Datex Capnomac, the Ohmeda CO_2 monitor, the Servomex paramagnetic analyser and GC were all checked for linearity before the study.

CALCULATIONS (fig. 1)

Dilution factor for end-expiratory gas

The inspired partial pressure of isoflurane, $P\text{I}_{\text{iso}}$, was calculated as follows:

$$P\text{I}_{\text{iso}} = F\text{I}_{\text{iso}}(P\text{B} - P\text{H}_2\text{O})$$

where $F\text{I}_{\text{iso}}$ = fractional inspired concentration of isoflurane in dry gas; $P\text{B}$ = barometric pressure; $P\text{H}_2\text{O}$ = saturated vapour pressure of water at body temperature.

On the assumption that the alveolar deadspace gas has the same composition as inspired gas, the dilution factor for end-expiratory gas by alveolar deadspace gas is:

$$\frac{P\text{A}_{\text{CO}_2} - P\text{E}'_{\text{CO}_2}}{P\text{A}_{\text{CO}_2} - P\text{I}_{\text{CO}_2}} \qquad (1)$$

where $P\text{A}_{\text{CO}_2}$ = alveolar $P\text{CO}_2$; $P\text{E}'_{\text{CO}_2}$ = end-expired $P\text{CO}_2$; $P\text{I}_{\text{CO}_2}$ = inspired $P\text{CO}_2$.

On the assumptions that $Pa_{\text{CO}_2} = P\text{A}_{\text{CO}_2}$ and $P\text{I}_{\text{CO}_2} = 0$, then:

$$\text{dilution factor (dil)} = \frac{Pa_{\text{CO}_2} - P\text{E}'_{\text{CO}_2}}{Pa_{\text{CO}_2}} \qquad (2)$$

where Pa_{CO_2} = arterial $P\text{CO}_2$.

Equation (1) was then applied to isoflurane and the ideal alveolar partial pressure of isoflurane was then derived as:

$$P\text{A}_{\text{iso}} = \frac{P\text{E}'_{\text{iso}} - (\text{dil} \times P\text{I}_{\text{iso}})}{1 - \text{dil}}$$

where $P\text{A}_{\text{iso}}$ = alveolar Piso; $P\text{E}'_{\text{iso}}$ = end-expiratory Piso; $P\text{I}_{\text{iso}}$ = inspired Piso.

Dilution factor for arterial blood

The shunt fraction was calculated using the classical shunt equation, deriving arterial and mixed venous oxygen content from $S\text{O}_2$, $P\text{O}_2$ and haemoglobin concentration as described above:

$$\text{Shunt fraction} = \frac{Cc'_{\text{O}_2} - Ca_{\text{O}_2}}{Cc'_{\text{O}_2} - C\bar{v}_{\text{O}_2}}$$

where Cc'_{O_2} = pulmonary end-capillary blood oxygen content; Ca_{O_2} = arterial blood oxygen content and $C\bar{v}_{\text{O}_2}$ = mixed venous blood oxygen content. The shunt equation was applied to isoflurane and the pulmonary end-capillary partial pressure of isoflurane (Pc'_{iso}) derived as:

$$Pc'_{\text{iso}} = \frac{Pa_{\text{iso}} - (\text{shunt} \times P\bar{v}_{\text{iso}})}{1 - \text{shunt}}$$

where Pa_{iso} = arterial Piso; $P\bar{v}_{\text{iso}}$ = mixed venous Piso.

The data are shown as mean (SE) and where appropriate the difference between means was tested using Student's t test.

RESULTS

After 25 min with a constant inspired isoflurane concentration, a relatively steady state was achieved with the end-expired isoflurane concentration changing by less than 0.02% during the last 15 min of this period, and by less than 0.01% during the 5-min period of measurements. Inspired Piso was 0.69 (0.05) kPa and end-expiratory Piso was 0.52 (0.04) kPa, giving an end-expired: inspired ratio of 0.75 (0.02). Arterial Piso was 0.35 (0.03) kPa, with an arterial: end-expired ratio of 0.66 (0.02). Piso of the mixed venous blood was 0.22 (0.03) kPa (table I).

At the time of the isoflurane measurements, the physiological deadspace (including apparatus deadspace) was 53.6 (3.1)%, and the arterial–end-expiratory $P\text{CO}_2$ difference 0.56 (0.16) kPa. Calculated for carbon dioxide, the dilution factor for alveolar gas by alveolar deadspace was 11.58 (3.39)%. The shunt fraction was 14.8 (4.74)%, with an ideal alveolar to arterial $P\text{O}_2$ gradient of 14.2 (2.21) kPa.

Derived values

Applying the alveolar deadspace dilution factor to isoflurane, the calculated ideal alveolar Piso would be 0.50 (0.04) kPa; this was 96 (1.0)% of the end-expired value, a difference between the two of only 0.02 kPa.

Applying the shunt fraction to isoflurane, the pulmonary end-capillary Piso would be 0.38 (0.04) kPa which is only 0.03 kPa greater than the arterial Piso. The residual, unexplained, difference between ideal alveolar Piso and pulmonary end-capillary Piso was 0.12 (0.01) kPa. The difference from zero for this gradient was highly significant ($P < 0.001$) (fig. 2).

DISCUSSION

The presence of an end-expiratory to arterial anaesthetic partial pressure difference has been demonstrated for several volatile anaesthetic agents in healthy subjects. Our mean measured arterial: end-expired Piso ratio for isoflurane was 0.66 (0.02), which is less than the values obtained by Frei and colleagues [4] and Dwyer and colleagues [5], but we are in full agreement that a substantial difference exists. This gradient has been attributed hitherto to the increased alveolar deadspace and venous admixture (shunt) found in anaesthetized patients [10–14].

In the present study, the values for physiological

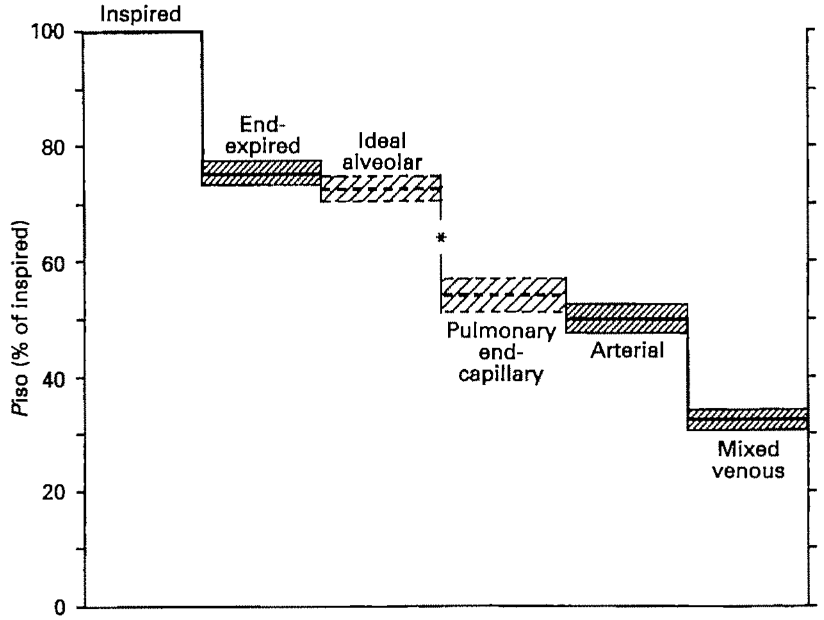

FIG. 2. Cascade of isoflurane partial pressures (*P*iso) from inspired gas to mixed venous return expressed as a percentage of inspired partial pressure. Solid lines and close hatching show measured values (mean, SEM). Dashed lines and wide hatching show *calculated* values (mean, SEM). *Highlights the unexplained difference between ideal alveolar and pulmonary end-capillary partial pressures.

deadspace and the arterial–end-expiratory $P\text{CO}_2$ difference were typical for anaesthetized patients with tracheal tube and apparatus deadspace included [15]. The alveolar deadspace dilution factor of 11.6 % can have little effect on the ideal alveolar–end-expiratory difference, partly because it is normally quite small during anaesthesia and partly because the alveolar deadspace gas would contain isoflurane approximating in composition to the inspired gas. Thus the ideal alveolar *P*iso is very little less than the measured end-expired value: only 0.02 kPa in the present study. Similar considerations would apply to ventilation of alveolar units of large (but not infinite) ventilation: perfusion ratio simulating a true alvolar deadspace.

The mean shunt in this study accords very closely with previous observations on anaesthetized patients in the age range 57–79 yr [12]. If the three-compartment model is applied to isoflurane, the pulmonary end-capillary *P*iso would be only 0.03 kPa greater than the arterial *P*iso. This is to be expected because, in common with carbon dioxide, *P*iso bears a constant relation to content and the partial pressures in mixed venous and arterial blood are not greatly different. It is only because of its alinear dissociation curve that oxygen has so large an alveolar–arterial $P\text{O}_2$ difference in the presence of a shunt. Thus the corrections for shunt and deadspace together account for only 33 % of the total end-expired to arterial *P*iso difference (fig. 2, table I).

Our analysis has followed the classical three-compartment model of the lung suggested by Riley and Cournand [16]. Although this approach treats relative maldistribution of ventilation and perfusion as though it contributed to alveolar deadspace and shunt, it gives values for these parameters which permit satisfactory prediction of arterial $P\text{CO}_2$ and $P\text{O}_2$ in a wide range of clinical situations. In this analysis some approximations are made, and it remains to consider how these effect the validity of our conclusions.

The Riley analysis assumes that the alveolar deadspace gas contains gas which has the same composition as inspired gas. In fact, a small quantity of end-expiratory gas from the anatomical deadspace must be re-inhaled into the alveolar deadspace. If, as seems likely, this effect were to increase the $P\text{CO}_2$ of the alveolar deadspace gas by 0.4 kPa, then the mean value for the alveolar deadspace dilution factor would be increased by about 0.9 % (equation (1)). This would result in a reduction in the calculated ideal alveolar *P*iso of about 0.002 kPa (equation (2)). However, the Riley analysis also assumes that ideal alveolar $P\text{CO}_2$ equals arterial $P\text{CO}_2$. This is not so when there is an appreciable shunt, but the effect is usually very small because the mixed venous–arterial $P\text{CO}_2$ difference is normally only about 10 % of the arterial–mixed venous $P\text{O}_2$ difference, and much less when the concentration of oxygen in the inspired gas is increased. A mean shunt of 14.8 %, with our measured values for mean arterial and mixed venous $P\text{CO}_2$, would reduce the mean ideal alveolar $P\text{CO}_2$ from an assumed 4.9 kPa to 4.8 kPa. Substitution of the corrected value into equation (1) reduces the mean alveolar deadspace dilution factor by about 2 %, increasing the calculated ideal alveolar *P*iso by about 0.004 kPa. This offsets the previous correction and the net result is a very small *increase* (0.002 kPa) in the calculated ideal alveolar *P*iso.

Calculation of shunt in the Riley analysis depends on the value for ideal alveolar $P\text{O}_2$, which is derived from the ideal alveolar $P\text{CO}_2$, conventionally assumed to be equal to the arterial $P\text{CO}_2$. Applying the correction to the alveolar $P\text{CO}_2$ derived in the previous paragraph, the calculated shunt would be decreased by less than 0.1 %. This would increase the derived pulmonary end-capillary *P*iso by a negligible quantity—less than 0.0002 kPa. This would have no significant effect on the residual gradient.

Anaesthesia results in compression atelectasis of dependent lung zones, with a true shunt which relates to the amount of atelectasis observed by computed tomography [17]. However, during anaesthesia about 50% of the observed alveolar to arterial $P\text{CO}_2$ difference and the venous admixture (calculated from the shunt equation) is explained by an increased spread of ventilation:perfusion ratios and, in particular, as a result of perfusing alveolar units with ventilation:perfusion ratios in the range 0.005–0.1 [11, 12, 18]. This has a much greater effect on $P\text{O}_2$ than on either $P\text{CO}_2$ or *P*iso because of the upward convexity of the oxyhaemoglobin dissociation curve. However, this factor is considered in calculating the equivalent "shunt effect" of perfusion in areas of low ventilation:perfusion ratios.

Dueck and colleagues [19] have argued that the method of analysing $V\text{A}/Q$ relations in the lungs used by Nunn, Bergman and Coleman [12] and in our present study has limitations because calculated shunt increases with smaller inspired oxygen concentration. However, the range of fractional inspired concentrations of oxygen used in our study was 0.34–0.50 and it is likely that most of the calculated venous admixture represents true shunt. Even if our calculations of shunt are underestimates, a large shunt, in the region of 50%, would be required to explain the observed end-expired–arterial *P*iso difference. In spite of the limitations of the three-compartment model, it seems improbable that abnormal distribution of ventilation:perfusion ratios, sufficient to cause the observed alveolar–arterial $P\text{O}_2$ difference, could explain more than a small fraction of the observed end-expiratory–arterial *P*iso difference.

If there is indeed a finite ideal alveolar–pulmonary end-capillary *P*iso difference, there are two possible explanations: there could be resistance to transfer through the alveolar capillary membrane; or isoflurane may not achieve uniform distribution throughout the alveoli during the ventilatory cycle. It is difficult to say how the physical properties of isoflurane could influence its ease of passage through the alveolar–capillary membrane. There is no measurable impairment of oxygen or carbon dioxide, except under conditions of maximal exercise at decreased inspired $P\text{O}_2$. For isoflurane, both water and lipid solubilities are greater than those of oxygen, which should favour its passage through the membrane. However, its molecular weight is much greater.

Gas mixing within the alveoli occurs predominantly by diffusion and the rate at which a gas diffuses is inversely proportional to the square root of its molecular weight. Under normal circumstances, incomplete mixing of gases such as oxygen and carbon dioxide is unlikely to occur. The average diameter of the human alveolus at functional residual capacity is about 200 µm and it is likely that mixing of gases of low molecular weight is almost instantaneous over the very small distance from the centre to the periphery [20]. However, this may not be the case for isoflurane or other anaesthetics of relatively high molecular weight. Georg and colleagues [21] studied diffusion differences in the gas phase of the lungs of normal and emphysematous subjects using three inert gases of widely different molecular weights and found that the ratio of heavier to lighter gas varied with the volume of expired gas. These differences were exaggerated in emphysematous subjects. Further evidence that the changes in ratio are the result of differing rates of gas diffusion comes from breath-holding experiments: when a breath is held for 30 s the ratios in the expired gas are independent of the volume expired [22]. Robertson, Whitehead and Hlastala [23] observed a difference in the retention of isoflurane (184.5 Da) and acetylene (26 Da) during its passage from blood to expired air. This could not be explained by differences in partition coefficients, and they concluded that it was consistent with a diffusion-related impairment of gas exchange. In support of this view, they cited several authors who had reported differences in anatomical deadspace as measured with gases of markedly different molecular weight.

This evidence suggests that some volatile anaesthetics may not be uniformly distributed throughout the alveolus and these inhomogeneities may make some contribution to the gradient between ideal alveolar gas and pulmonary end-capillary blood. It is likely that this gradient will differ for different anaesthetics. For nitrous oxide, Eger and colleagues [24] found a $Pa{:}P\text{E}'$ ratio of 0.98 after 8 min, implying that when deadspace and shunt have been accounted for, there is no residual gradient.

Our results and those of Frei and colleagues [4] and Dwyer and colleagues [5] show clearly that end-expiratory partial pressures of some volatile anaesthetics are greater than those in arterial blood, and must be greater than at the site of action in the brain. Thus MAC is related to values which differ significantly from those at the site of action. Nevertheless, it is not possible to measure partial pressures at the site of action, nor is it feasible to monitor arterial partial pressure in the present state of technology. It is therefore fortunate that the arterial:end-expiratory *P*iso ratio was found to be remarkably constant at 0.66 (0.02). Thus measuring end-expiratory partial pressures in relation to MAC values is a valid method to monitor the depth of anaesthesia. However, comparison of MAC values as an absolute measure of potency might be questioned if the arterial:end-expired ratios are significantly different, as seems to be the case at least for nitrous oxide and isoflurane.

To our knowledge, mixed venous concentrations of an anaesthetic have not been measured before in humans and on average they were 40% smaller than the arterial value. However, it can be predicted that, in humans, it would take several days of anaesthesia for the mixed venous concentration of isoflurane to equal that of arterial blood, when the inspired–end-expiratory–arterial gradient would disappear. The presence of this gradient for isoflurane is therefore likely to persist even during prolonged anaesthesia.

In conclusion, we suggest that the effects of shunt and deadspace are small and the main reason for the end-expired to arterial partial pressure gradient for isoflurane observed by Frei and colleagues [4], Dwyer and colleagues [5] and ourselves may be the failure to achieve uniform distribution within the alveolus. This will impede changes in anaesthetic partial pressure in blood and therefore tissues, thus hindering the attainment and reversal of the anaesthetic state. Further studies on other volatile anaesthetics are needed.

COMPARISON OF THE SEDATIVE AND AMNESIC EFFECTS OF MIDAZOLAM AND PROPOFOL

M. R. POLSTER, P. A. GRAY, G. O'SULLIVAN, R. A. McCARTHY AND G. R. PARK

SUMMARY

We have compared the sedative and amnesic effects of midazolam and propofol in 35 volunteers. Sedation was measured by simple reaction time immediately before and after a bolus injection and 1 h after the commencement of a subsequent continuous infusion. Memory was measured three times using two memory tests: perceptual facilitation provided an implicit memory measure and recognition provided an explicit memory measure. Propofol and midazolam had similar sedative effects both immediately after bolus doses and after 1-h continuous infusions of the drugs. In contrast, midazolam had a more profound amnesic effect than propofol on the recognition memory test. The drugs had little effect on performance with the implicit memory test. Performance on the memory tests was unrelated to sedation. (Br. J. Anaesth. 1993; **70**: 612–616)

KEY WORDS

Hypnotics, benzodiazepines: midazolam. Anaesthetics, intravenous: propofol. Memory: amnesia.

The amnesic effects of midazolam have been documented [1, 2], but there are only clinical observations to suggest that propofol might possess amnesic properties [3]. This study has compared these two drugs directly to establish their relative potency as amnesia producing agents.

Memory may be dependent partly on the subject's level of arousal or alertness at the time of learning. This makes it imperative to use an independent cognitive measure of sedation in order to eliminate the possibility that the amnesic effects are related to sedation. In this study, we have therefore used a simple reaction time test to measure and maintain the same level of sedation for the two agents.

Neuropsychological and cognitive analyses have indicated that memory should not be considered as a single entity [4–6]. A major distinction has been drawn between conventional memory tests such as recall and recognition ("explicit" memory tests), and tests that do not require the subject to recollect overtly the previous learning episode ("implicit" memory tests) [7]. For example, if subjects are asked to identify a degraded stimulus on two occasions, they often do so more easily on the second occasion, even if they do not remember the first presentation. Such an effect can be labelled perceptual facilitation, and is independent of recognition memory. In view of the evidence for this dissociation, we thought it was important to establish what type of memory was affected by propofol and midazolam.

One of three stages of the memory process—encoding, storage or retrieval—may be affected by the drugs. In order to isolate these stages of memory processing, it was necessary to determine if memory loss is a manifestation of the so-called state dependency phenomenon which is seen when subjects cannot recall material under a pharmacological condition that differs from the state at learning, but then recall the same information when the original learning condition is re-established.

Therefore we have compared the effects of propofol and midazolam on implicit and explicit memory under conditions in which sedation was matched by simple reaction time. The design was refined further to include analyses of state dependency and an evaluation of the stage of memory processing most affected by these drugs. Previous studies on benzodiazepines led us to expect a major effect of midazolam on explicit memory, but its effects on implicit memory remain undetermined [8, 9]. The literature also suggests that benzodiazepines in general (and therefore midazolam in particular) may act as a primary amnesogenic agent rather than as a "state dependent" influence [10].

SUBJECTS AND METHODS

We studied 35 healthy (ASA I) volunteers, aged 18–40 yr, in two sessions 1 week apart. They were allocated randomly to receive midazolam, propofol or placebo in each of two testing sessions. This created seven groups of five subjects necessary to test for state-dependent effects: placebo–placebo, placebo–propofol, placebo–midazolam, propofol–

placebo, propofol–propofol; midazolam–placebo; midazolam–midazolam. Ethics Committee approval was received, and written informed consent was obtained from each volunteer. There were no differences in age distribution for the seven groups.

Subjects were presented with a series of tests before and during administration of midazolam, propofol or placebo. Table I provides a summary of the procedure on the first day; the same procedure was used on the second day, except that there was no presentation before giving the drug. Undiluted propofol 10 mg ml^{-1}, midazolam 1 mg ml^{-1} diluted with 0.9% saline, or placebo (0.9% saline) was administered using a Grazeby syringe pump via an i.v. cannula in the non-dominant arm. Both the subject and the cognitive experimenter were blind to the solution being administered.

Sedative effect of propofol and midazolam

At each measurement of reaction time, subjects were presented with a block of 48 trials using an Apple Macintosh computer and the commercially available PsychLab program [11]. Each trial consisted of a warning signal (the word "READY") presented for 500 ms, followed by a variable foreperiod (a blank screen) for 500, 1000 or 1500 ms, followed by a target stimulus (the letter X). Within each block of 48 trials, there were 16 of each foreperiod interval, distributed randomly, but no interval occurred more than three times consecutively. Subjects used the dominant hand to press the space bar on the keyboard as soon as the X appeared. After an interval of 2.5 s, the next trial began with the presentation of the warning signal. Reaction time was recorded to the nearest millisecond.

Subjects were presented with one block immediately before any injections. Block two was presented immediately after the initial bolus dose of midazolam 0.04 mg kg^{-1}, propofol 0.07 mg kg^{-1} or placebo (0.9% saline), and was used only to determine if a second bolus dose would be administered. Block three was administered after a second bolus dose of midazolam, propofol or placebo if required and measured the peak sedative effects of the two drugs. Block four was administered 1 h later, during which time a continuous i.v. infusion was administered (midazolam 0.035 mg kg^{-1} h^{-1}; propofol 1.27 mg kg^{-1} h^{-1}). The initial infusion rates were midazolam 0.04 mg kg^{-1} h^{-1} and propofol 1.5 mg kg^{-1} h^{-1}. These doses were scaled down from data obtained by Wilson, Mackenzie and Grant [3], making allowances for the differences in age and ASA grade and were adjusted if subjects were unable to complete the simple reaction time task.

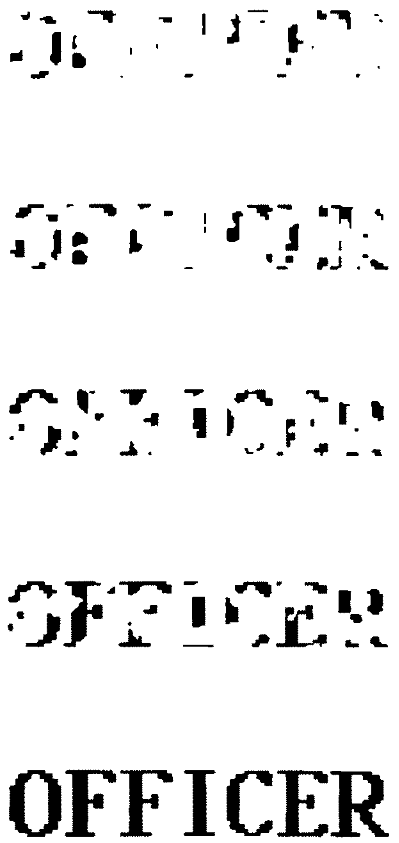

FIG. 1. Example of word fragmentation.

Amnesic effects of propofol and midazolam

Five sets of 20 words were created. Each word was presented at five levels of fragmentation ranging from one (very degraded) through to five (complete word) (fig. 1). Each version of the word was shown for up to 5 s, during which time the volunteer was asked to identify it. If it was not named the next less degraded version was shown. This procedure continued until the subject identified the word correctly. The subject's response to each version and the number of versions required to identify the word were recorded on the computer. The word lists were presented in a counterbalanced design, such that list one occurred equally often as a test item across subjects.

Each subject saw 20 fragmented words before being given propofol, midazolam or placebo on the first day of testing. Memory was tested for these items 1 h later during the continual infusion, by presenting the same words mixed with a second set of 20 words, which served as distractor items. This test served as a baseline measure of performance. Memory for the second stimulus set was tested approximately 1 h later, mixed with a third list of 20 words that served as distractors. This memory test measured the ability of subjects to encode new information under the influence of the drugs. Memory for the third set was tested 7 days later by presenting the same items mixed with another new set of 20 words which served as distractor items.

Two measures of memory were obtained in each test: perceptual facilitation on items presented twice, and recognition. Identifying the word in fewer versions on the second presentation is evidence for the effect (or memory) of the previous presentation, and is termed perceptual facilitation. Because it does not require conscious recollection, perceptual facilitation is considered an implicit memory test. Recognition memory was measured by having subjects respond Yes, Probably Yes, Probably No and No, and provided an index of explicit memory. The non-parametric sensitivity measure, *A*, was then calculated as a measure of recognition memory [12].

Unless otherwise stated, all the data were analysed using mixed analyses of variance and significance levels were set at $P < 0.05$.

RESULTS

Sedative effects of propofol and midazolam

Response times in the range 150–1000 ms were included in the analysis, thereby excluding trials on which the subject was extremely slow to respond and trials on which the stimulus was anticipated. Harmonic means were calculated for each subject's residual data points [13]. Figure 2 shows that there was no difference in response time performance across the three groups of subjects before the drugs were given ($P > 0.05$). Immediately after the drug was given, the midazolam and propofol groups had significantly increased reaction times compared with placebo ($P < 0.001$), but the midazolam and propofol groups did not differ ($P > 0.05$). Finally, the effects of both drugs on response time dissipated to a similar extent (returning to baseline) over the course of 1 h, despite continuous infusion of the drugs ($P > 0.05$). The initial bolus dose and infusions of both midazolam and propofol produced similar effects on response time, showing that both groups were sedated to the same level throughout the study.

Amnesic effects of propofol and midazolam

Three main analyses were conducted on the memory data. The first compared memory performance for the treatment groups on material presented before the drug was given and tested immediately after the bolus dose of the drugs (during the peak effect). Analysis one, therefore, gave a measure of the effects of drugs on memory retrieval. Analysis two investigated memory for stimuli presented after the first bolus of the drug and tested 1 h later, whilst the subject was still receiving the drug. This analysis provided a measure of the effects of the drugs on memory encoding and storage. Analysis three evaluated subjects' performances during a continuous infusion of the drug after a 7-day drug-free interval and provided a measure of the long-term effects of the drugs. The partially overlapping design also allowed a further test of the possibility that drugs affect the retrieval of information.

Analysis 1. Table II presents the data for recognition and perceptual facilitation for the items that were shown before the drug was given and tested under the influence of the drugs during the first session. It shows no effects of drug condition on either test (all $P > 0.05$). These findings indicate that neither propofol nor midazolam impaired the retrieval processes required for recognition or perceptual facilitation to occur.

Analysis 2. Table III presents the data for recognition and perceptual facilitation for the items that were both presented *and* tested under the influence of the drugs during the first experimental session. It shows that both midazolam and propofol significantly impaired performance on the explicit (recognition) memory test relative to the placebo group ($P < 0.05$). Additionally, midazolam produced significantly greater amnesia than propofol

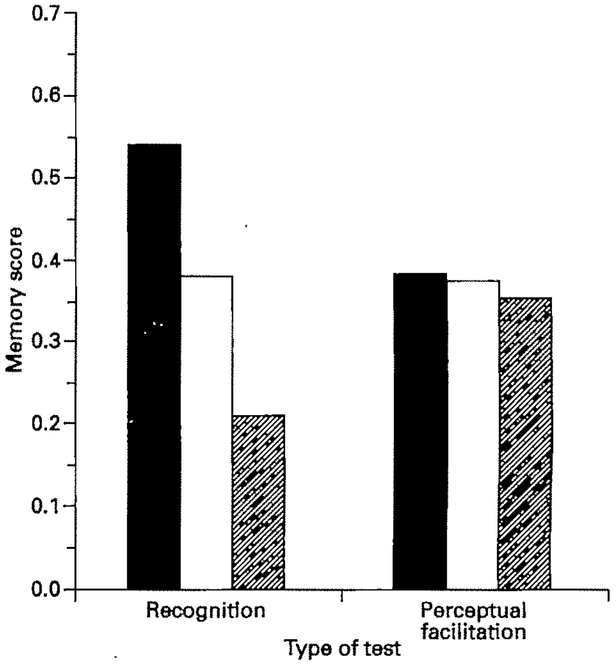

FIG. 2. Recognition and perceptual facilitation for words after a 7-day retention interval by drug condition at encoding. ■ = Placebo; □ = propofol; ▨ = midazolam.

TABLE II. *Recognition and perceptual facilitation scores (mean (SD)) for fragmented words: pre-drug acquisition*

Condition	Recognition (*A*)	Perceptual facilitation
Placebo	0.77 (0.15)	0.48 (0.13)
Propofol	0.78 (0.26)	0.48 (0.12)
Midazolam	0.75 (0.19)	0.41 (0.15)

TABLE III. *Recognition and perceptual facilitation scores (mean (SD)) for fragmented words: post-drug acquisition*

Condition	Recognition (*A*)	Perceptual facilitation
Placebo	0.79 (0.16)	0.46 (0.10)
Propofol	0.68 (0.26)	0.47 (0.16)
Midazolam	0.51 (0.23)	0.38 (0.11)

TABLE IV. *Recognition and perceptual facilitation scores (mean (SD)) for fragmented words: 7-day retention interval*

Condition	Recognition (*A*)	Perceptual facilitation
Placebo	0.54 (0.17)	0.38 (0.18)
Propofol	0.38 (0.24)	0.37 (0.13)
Midazolam	0.21 (0.13)	0.35 (0.17)

TABLE V. *Analysis of state dependency in recognition and memory tests (mean (SD))*

	Overlapping	Non-overlapping
Recognition	0.35 (0.27)	0.44 (0.19)
Perceptual facilitation	0.39 (0.16)	0.35 (0.16)

($P < 0.05$). In contrast, there was no difference between the groups in the implicit memory (perceptual facilitation) test ($P > 0.05$). These analyses suggest that both midazolam and propofol had an effect on recognition memory, but little or no effect on perceptual facilitation. Furthermore, it appears that the amnesic effect of midazolam was more profound than that of propofol.

Analysis 3. The data from the items tested after a 7-day retention interval were analysed according to the subject's condition at the time of stimulus study and at the time of stimulus test. An influence of the drugs on memory storage would be associated with an effect based on the subject's condition at the time of study, whereas an effect on retrieval would be more apparent when the data were analysed according to the subject's condition when tested. The analysis conducted based on the subject's condition at the time of test revealed no significant effects (all $P > 0.05$). This analysis replicates and extends the findings from Analysis 1, in showing that the drugs did not affect memory retrieval.

The findings for the analysis conducted according to the subject's condition at the time of encoding were consistent with the within-drug analyses (see Analysis 2). Table IV presents the results for the three drug conditions. It shows that both midazolam and propofol significantly impaired performance in the explicit (recognition) memory test relative to the placebo group ($P < 0.05$) and that midazolam produced significantly greater amnesia than propofol ($P < 0.05$). There was no difference between groups in the implicit memory (perceptual facilitation) test ($P > 0.05$). These analyses show there was a stepwise amnesic effect on the recognition test with the best performance in the placebo group, an intermediate level of performance in the propofol group, and the most profound amnesia in the midazolam group.

Table V presents the same data in a different form to address the issue of state-dependency. The three groups in which there was an overlap in the conditions on the two days (placebo–placebo, propofol–propofol, midazolam–midazolam) were compared with the four groups in which there was no overlap (placebo–propofol, propofol–placebo, placebo–midazolam, midazolam–placebo). State-dependency would be observed if performance in the overlapping condition was better than performance in the non-overlapping condition. However, there was no difference and so there was no evidence for state-dependent memory effects on either the recognition memory test or the perceptual facilitation test ($P > 0.05$).

DISCUSSION

We have shown that midazolam and propofol had similar cognitive effects. Both drugs increased reponse times to a similar degree after an initial bolus dose of the drug and these effects dissipated to similar extent after 1 h during a continuous i.v. infusion of the drug. These results show that the bolus doses and infusion rates given to the volunteers produced similar levels of sedation throughout the study.

It has been suggested that memory is dependent on the degree of sedation [14, 15]. Despite similar levels of sedation, midazolam and propofol produced different levels of amnesia. On every recognition memory test, performance was worse in the midazolam group than in the propofol group. Furthermore, response times had returned to normal when the material was presented for the 7-day retention interval (Analysis 3). At this time there was evidence of a profound amnesia for both drugs, even though reaction times were normal. These findings show that the amnesic effects could not be attributed to differences in sedation.

Both drugs impaired performance on the explicit recognition memory test, but neither midazolam nor propofol affected performance on the perceptual facilitation (implicit memory) task. Despite this qualitative similarity, midazolam and propofol had different quantitative effects—midazolam produced a more profound amnesia than propofol with the recognition memory tests. This difference in memory performance cannot be attributed easily to greater impairment in general processing produced by midazolam (as reflected by a clinical difference in sedation) because response times for the two groups of subjects were similar.

Both drugs impaired processes associated with the storage or consolidation of new information, and neither drug affected processes associated with retrieval. There was no evidence for a state-dependent memory effect with propofol or midazolam with either task (implicit or explicit memory test), or when all the conditions were combined. Therefore we have shown a selective explicit memory deficit for information that was learned under the influence of the drugs, and that this deficit was more severe for midazolam than for propofol. These results confirm the clinical reports that propofol has amnesic properties [3], but that they are not as profound as those of midazolam.

Work in the area of memory and anaesthesia has suggested the possibility that intraoperative memories can be formed without conscious recollection [16–18]. The apparent inability of midazolam and propofol to impair implicit memory as measured by perceptual facilitation in this study suggests that the formation of such "unconscious" memories cannot be dismissed.

ACKNOWLEDGEMENTS

We thank ICI, Alderley Park, Manchester and ICI Pharma, Paris for their support with funding for this study. R.McC. was supported in part by a grant from Leverhulme Trust to King's College, Cambridge.

PLASMA CONCENTRATIONS OF MIDAZOLAM AFTER I.V., NASAL OR RECTAL ADMINISTRATION IN CHILDREN

J.-M. MALINOVSKY, C. LEJUS, F. SERVIN, J.-Y. LEPAGE, Y. LE NORMAND, S. TESTA, A. COZIAN AND M. PINAUD

SUMMARY

Midazolam is used frequently for premedication in children, preferably by non-parenteral administration. We have compared plasma concentrations of midazolam after nasal, rectal and i.v. administration in 45 children (aged 2–9 yr; weight 10–30 kg) undergoing minor urological surgery. General anaesthesia consisted of spontaneous respiration of halothane and nitrous oxide in oxygen via a face mask. After administration of atropine and fentanyl i.v., children were allocated randomly to receive midazolam 0.2 mg kg^{-1} by the nasal, rectal or i.v. route. In the nasal group, children received 50 % of the dose of midazolam in each nostril. In the rectal group, midazolam was given rectally via a cannula. Venous blood samples were obtained before and up to 360 min after administration of the drug. Plasma concentrations of midazolam were measured by gas chromatography and electron capture detection. After nasal and rectal administration, midazolam Cmax was 182 (SD 57) ng ml^{-1} within 12.6 (5.9) min, and 48 (16) ng ml^{-1} within 12.1 (6.4) min, respectively. Rectal administration resulted in smaller plasma concentrations. In the nasal group, a plasma concentration of midazolam 100 ng ml^{-1} occurred at about 6 min. After 45 min, the concentration curves after i.v. and nasal midazolam were similar. (Br. J. Anaesth. 1993; **70**: 617–620)

KEY WORDS
Hypnotics, benzodiazepines: midazolam.

In children, fear of venepuncture and separation from parents may produce stormy induction of anaesthesia [1]. In these circumstances, premedication helps to decrease anxiety and minimize psychological trauma [2]. Various premedications and delivery systems have been developed using different routes of administration.

Benzodiazepines are used routinely for premedication in children [3, 4]. Most of these drugs have prolonged effects associated with slow elimination. Midazolam, a water soluble, short-acting 1,4-benzodiazepine, with a rapid elimination in adults, is frequently used in children as premedication by the i.m. [3], rectal [4] or oral [5] route. Pharmacokinetic studies of midazolam administered by these routes have shown slow onset [5], small peak plasma concentrations [4, 5] and low bioavailability [4, 5].

Nasal administration has been described for sufentanil [6], ketamine [7] and midazolam [8]. For nasal midazolam, there is only one report of plasma concentrations over 90 min in children during general anaesthesia [9]. The aim of this study was to compare plasma concentrations of midazolam administered after nasal, rectal and i.v. administration in healthy children.

METHODS AND PATIENTS

After obtaining institutional approval and informed consent of parents, we studied 45 ASA I children (ages 2–9 yr; weights 10–30 kg) undergoing minor urological surgery. Exclusion criteria were rhinopharyngitis, digestive disorders, treatment with theophylline, H_2 receptor antagonists, β-lactamines associated with clavulanic acid and aminoglycosides, and anaesthetic procedures involving barbiturate administration.

Anaesthesia was induced with halothane and nitrous oxide in oxygen via a face mask. Anaesthesia was maintained with halothane (expired concentration approximately 1 %) without tracheal intubation. After cannulation of a vein using a 20-gauge cannula and i.v. injection of fentanyl 2 μg kg^{-1} and atropine 15 μg kg^{-1}, midazolam was administered. Children were allocated randomly to three groups: group N ($n = 15$) received nasal midazolam 0.2 mg kg^{-1} as reported previously [8]; group V ($n = 15$) received i.v. midazolam 0.2 mg kg^{-1}; and group R ($n = 15$) received rectal midazolam 0.2 mg kg^{-1}. The drug was diluted in saline solution to a 0.1 % concentration for all routes. In group N, 50 % of each dose was administered (a few drops) in each

nostril within 15 s. Rectal administration was performed using a short, air-washed cannula. After i.v. administrations, the cannula was flushed with physiological saline 10 ml. In all groups, heart rate, arterial pressure, ventilatory frequency and finger pulse oximetry were monitored continuously.

Venous blood samples (3 ml) were obtained before administration and 2, 4, 6, 8, 10, 15, 20, 30, 45, 60, 120, 180, 240 and 360 min after administration of midazolam. Plasma was separated by centrifugation at 4500 *g* and stored at -20 °C until analysis. Plasma concentration of midazolam was measured by gas–liquid chromatography (Delsi model 300 gas chromatograph, Delsi-Nermag Instrument, Argenteuil, France) using an adaptation of clonazepam microdetermination with capillary column and electron-capture detection [9]. Internal standard was prazepam. The smallest value measured was 1 ng ml^{-1} in plasma, with a single deposit and a signal-to-noise ratio of 2:1. The calibration curve was linear within the range 0–200 ng ml^{-1}. Greater concentrations required dilution of plasma samples before extraction. The main metabolite of midazolam, α-hydroxymidazolam, was not detected by the assay. The coefficients of variation were less than 7% (intraassay and interassay).

Statistical comparisons were carried out by ANOVA for continuous variable (age, weight, *C*max and *t*Cmax). $P < 0.05$ was considered significant.

RESULTS

Patient characteristics are listed in table I. No child experienced nasal disturbances and after rectal midazolam there was no defaecation or rectal lesion. There were no significant haemodynamic changes in the three groups after administration of midazolam. Ventilatory frequency was not reduced significantly 5 min after nasal or i.v. administration, and was unchanged throughout in group R. One of the 15 children had apnoea after i.v. administration of midazolam and required manually assisted ventilation for 5 min. No child had prolonged sedative effects after operation. In group V, three of 15, and in group R two out of 15, were excluded because of blood collection difficulties after 30 min.

*C*max and *t*Cmax in all groups are presented in table II. Figure 1 represents logarithmic concentration *vs* time curves after all routes of admin-

DISCUSSION

The present study is the first in which plasma concentrations of midazolam have been compared after i.v., nasal and rectal administration in children. Previous studies examined only one of these routes. Walberg, Wills and Eckert measured plasma concentrations after a smaller dose of midazolam (0.1 mg kg^{-1}) administered nasally in children undergoing cardiac surgery and blood samples were obtained for only 90 min after administration [10]. Saint-Maurice and colleagues studied rectal midazolam 0.3 mg kg^{-1} premedication in 16 children, but pharmacokinetic data were obtained in only nine, and there was no comparison with venous administration [4].

In the present study, anaesthesia comprised nitrous oxide, halothane and fentanyl. Halothane causes a decrease in hepatic blood flow and modification of hepatic enzyme function [11], and this may influence the metabolism of midazolam, increasing its plasma concentrations. Plasma concentrations may also be greater after nasal administration during general anaesthesia compared with awake children because midazolam is irritant. Nasal administration during general anaesthesia avoids coughing and sneezing with expulsion of part of the dose, so that if nasal absorption is not complete, the agent may be absorbed partly via the oral route. However, the supine position on the operating table produces nasal stasis and complete absorption via the nasal mucosa without any first pass hepatic metabolism.

Plasma concentrations were similar in groups N and V from 45 min after administration. In group R, plasma concentrations were constantly less than those in the two other groups, possibly because of first pass metabolism. The large variation in rectal pH in children may cause modification in chemical properties and altered absorption [12]. Most maturational changes occur within the first 1 yr of life, so that hepatic metabolism in older children is similar to that of adults.

The individual threshold plasma concentration of midazolam for sedation varies in the range 30–100 ng ml^{-1} in adults [13], but has not been determined in children. However, Wilton and colleagues [8] noted a calming effect within 5 min after nasal midazolam 0.2 mg kg^{-1} and this became significant within 10 min. Wilton's group used nasal midazolam 0.2 and 0.3 mg kg^{-1} as premedication [8] and found that the degree of sedation was similar. However, the 0.3-mg kg^{-1} dose required a larger volume, resulting in some expulsion of part of the dose. In our study with a nasal dose of 0.2 mg kg^{-1}, plasma concentrations reached 100 ng ml^{-1} or more within 6 min, *t*Cmax occurring at about 12 min.

The main metabolite of midazolam, α-hydroxymidazolam, which was not detected by our assay, has sedative properties and may facilitate rapid onset of sedation. As absorption via nasal mucosa is determined by the physical and chemical properties of a solution, the absorption of midazolam may differ when a lipophilic vehicle is used (the drops in our study contained a hydrophilic solution). Secretions caused by nasal irritation may also modify absorption, but rhinitis was not observed in our study, and all the children received atropine before midazolam was administered.

In children who received rectal midazolam, the time to reach a sedative threshold of 100 ng ml^{-1} was longer than that after nasal administration [4]. Yaster and colleagues [14] recommended a dose of midazolam up to 1 mg kg^{-1}, and Saint-Maurice and colleagues [4], using a dose of 0.3 mg kg^{-1}, observed a sedative effect within 20 min, with a *C*max of 100 ng ml^{-1} within 16 min. In the present study, plasma concentrations in group R were always less than 100 ng ml^{-1}. The smaller plasma concentrations after rectal administration may have been caused by first pass metabolism. Other agents such as ketamine may be administered rectally and the plasma concentrations [15] reflect first-pass hepatic metabolism so that the ketamine metabolite, norketamine, is present in greater concentrations than ketamine.

The plasma concentrations of midazolam were similar to those of sufentanil after nasal administration (*t*Cmax at about 10 min, *C*max 67% less than after i.v. administration) [6]. We found that, within 10 min after nasal midazolam, plasma concentrations were greater than 180 ng ml^{-1}, as great as plasma concentrations obtained within 30 min after i.m. [2] or oral [3] midazolam 0.2 mg kg^{-1}.

Our results in this pharmacokinetic study suggest that nasal administration of midazolam may be worth investigating for rapid premedication in children.

TRANSOESOPHAGEAL ECHOCARDIOGRAPHIC ASSESSMENT OF HAEMODYNAMIC FUNCTION DURING LAPAROSCOPIC CHOLECYSTECTOMY†

A. J. CUNNINGHAM, J. TURNER, S. ROSENBAUM AND T. RAFFERTY

SUMMARY

We have measured cardiovascular changes associated with insufflation of carbon dioxide and the reverse Trendelenburg position during laparoscopic cholecystectomy, using transoesophageal echocardiography in 13 healthy patients. End-tidal carbon dioxide values increased after insufflation of carbon dioxide, with values significantly ($P < 0.05$) increased after lateral tilt positioning. Creation of a pneumoperitoneum was associated with increases ($P < 0.05$) in left ventricular end-systolic wall stress, concomitant with increases ($P < 0.01$) in peak airway pressure and systemic arterial pressure. In addition, left ventricular end-diastolic area decreased ($P < 0.05$) after reverse Trendelenburg positioning. Left ventricular ejection fraction was maintained throughout the study. (Br. J. Anaesth. 1993; **70**: 621–625)

KEY WORDS

Measurement techniques: transoesophageal echocardiography. Surgery: laparoscopic cholecystectomy.

Laparoscopic cholecystectomy, described first by Phillipe Mouret in 1988 [1], was reported first in the literature by Perissat, Collet and Belliard [2] and refined and popularized in the United Kingdom by Nathanson, Shimi and Cuschiei [3]. Laparoscopic cholecystectomy has been reported to have the advantages of shorter hospital stay, more rapid return to normal activities, less pain associated with the small, limited incisions and less postoperative ileus compared with open laparotomy [4–6].

Indications for the procedure soon became more liberal after case reports confirmed its efficacy in patients with acute cholecystitis, and in association with obesity, pregnancy and previous abdominal surgery [7–9]. The laparoscopic surgical technique has been advocated for older patients who may have co-existing cardiac or pulmonary disease, or both [10]. Laparoscopic cholecystectomy involves longer periods of intraperitoneal insufflation of carbon dioxide than gynaecological procedures.

The objectives of this study were to assess changes in venous return, myocardial performance and afterload, as determined by transoesophageal echocardiographic assessment of left ventricular end-diastolic area (EDA), left ventricular ejection fraction (LVEF) and left ventricular end-systolic wall stress (LVESWS) in healthy patients undergoing laparoscopic cholecystectomy.

PATIENTS AND METHODS

After obtaining local Human Investigation Committee approval, we studied 13 healthy patients (ASA physical status I–II) undergoing laparoscopic cholecystectomy. All patients gave informed consent. Patients with a history or ECG changes suggestive of previous myocardial infarction or evidence of left ventricular dysfunction were excluded, as were patients with disease states that might preclude transoesophageal echocardiography—coagulation or bleeding diathesis and oesophageal pathology.

A standard anaesthetic technique was used for all patients. All subjects were admitted to hospital on the morning of surgery. Midazolam 1–3 mg was administered i.v. for preoperative sedation before induction of anaesthesia with thiopentone 4.0 mg kg^{-1} i.v.; vecuronium 0.1 mg kg^{-1} i.v. was given to facilitate tracheal intubation. Anaesthesia was maintained with 0.5–1.0% end-tidal isoflurane and 50% oxygen in air, with incremental bolus doses of i.v. fentanyl 1–2 μg kg^{-1}. A urinary bladder catheter and nasogastric tube were inserted.

Intraoperative monitoring included continuous ECG (leads II and V_5), systemic arterial pressure using an automated cuff (PCMS system, Spacelabs Inc., Redmond, WA), pulse oximetry (Spacelabs Inc., Redmond, WA), neuromuscular function, inspired oxygen fraction, peak airway pressure, oesophageal temperature and urinary output. Intermittent positive pressure ventilation (IPPV) was used using an Ohmeda 7810 volume cycled ventilator (BOC Healthcare Co., Madison WI), with an inspiratory flow rate of 25 litre min^{-1}, a ventilatory

frequency of 8 b.p.m., a tidal volume of 100 ml kg^{-1} and an inspiratory:expiratory (I:E) ratio of 1:2. A Perkins–Elmer Advantage mass spectrometer was used to measure end-tidal carbon dioxide tension (PE'_{CO_2}) and isoflurane concentrations. End-tidal isoflurane concentrations were maintained in the range 0.5–1.0%.

The operative technique involved i.p. insufflation of carbon dioxide via a Verres needle inserted into a small infra-umbilical incision, with the patient in a 15–20° Trendelenburg position. An electronic variable-flow insufflator terminated flow when an intra-abdominal pressure of 15 mm Hg was reached. A cannula was inserted in place of the needle to provide and maintain insufflation adequate for surgery. A video laparoscope was inserted through the cannula and the operative field was visualized. The patient's position was changed to steep reverse Trendelenburg, with left lateral tilt, to facilitate retraction of the gall bladder fundus. The cystic duct and cystic artery were identified and clamped. The gall bladder was removed by instruments introduced through canulae via three additional small (5–11 mm) skin incisions, including one to the right of the midline to avoid the falciform ligament and two right upper quadrant sites.

Heart rate (HR), systolic/diastolic and mean arterial pressures (SAP/DAP and MAP), and arterial oxygen saturation (Sp_{O_2}) were recorded 3 min before induction of anaesthesia. These variables, in addition to peak airway pressures and PE'_{CO_2} were also recorded at the following times: 3 min after induction of anaesthesia; 3 min before carbon dioxide insufflation; 1, 3 and 5 min after insufflation; after reverse Trendelenburg positioning and after left lateral tilt.

Two-dimensional echocardiographic data were obtained with a 5-MHz (64-element) transoesophageal, transverse plane phased array transducer (Imaging System 77020 Hewlett–Packard Corporation, Andover, MA) inserted after induction of anaesthesia and tracheal intubation. Transgastric short axis images were obtained at the previously described left ventricular mid papillary muscle level [11]. Image clarity was optimized by grey scale adjustment.

Measured variables included left ventricular cavity end-diastolic and end-systolic planimetered areas (EDA and ESA) [12] and M-mode determined end-systolic posterior and anterior wall thickness (WT). Derived variables included left ventricular ejection fraction (LVEF) and left ventricular end-systolic meridional wall stress (LVESWS) [13, 14]. An average of three consecutive sinus beats at end expiration was obtained for each value of EDA and ESA. End-diastole was indicated by the peak of the ECG R wave and end-systole was defined as the smallest endocardial area. Left ventricular ejection fraction was determined by the calculation ((EDA − ESA) × 100)/EDA. LVESWS was calculated by the formula: $0.334 \times P\ (D)/WT\ (1 + WT/D)$, where P = cuff systolic arterial pressure; D = left ventricular diameter and WT = wall thickness represented by the average of the anterior and posterior measurements.

Videotapes recorded in real time simultaneously with 1-cm calibration grids and an electrocardiogram were reviewed on an off-line analyser system providing forward, reverse, slow motion and freeze viewing formats. The areas of interest were traced by hand-held digitizer. Echocardiographic data were obtained before insufflation of carbon dioxide; 1, 3 and 5 min after insufflation; after reverse Trendelenburg position and after left lateral tilt. Measurement reproducibility was assessed by randomly selecting 25% of profiles for reanalysis. Intra- and interobserver variabilities did not exceed 8% and 12%, respectively.

Statistical methods

Paired Student's *t* tests and Pearson correlation coefficients were used to compare measured and derived cardiovascular and echocardiographic values before insufflation of carbon dioxide with values 1, 3 and 5 min after insufflation and after reverse Trendelenburg and lateral tilt position changes. Results are expressed as mean (SD). $P < 0.05$ was considered statistically significant.

RESULTS

We studied 13 patients (five male). Patients' mean age was 52 (17) yr (range 22–78 yr). The mean height and weight were 168 (8) cm and 80 (10) kg, respectively. Preinduction HR was 74 (17) beat min^{-1}, SAP 147 (21) mm Hg, DAP 83 (11) mm Hg, MAP 107 (16) mm Hg and Sp_{O_2} 97 (2)%.

There were no significant changes in either heart rate or arterial oxygen saturation after insufflation of carbon dioxide and changes in patient position. SAP, DAP and MAP were significantly ($P < 0.01$) greater 1, 3 and 5 min after insufflation of carbon dioxide, reverse Trendelenburg and lateral position changes, compared with the pre-insufflation values. PE'_{CO_2} values were greater after insufflation of carbon dioxide, but the values were significantly ($P < 0.05$) increased only after the lateral tilt position change. Peak airway pressures were significantly ($P = 0.0001$) greater than pre-insufflation values at 1, 3 and 5 min after insufflation and after reverse Trendelenburg and lateral tilt positioning (table I).

Left ventricular ESA and LVEF were unchanged after insufflation of carbon dioxide and changes in patient position. Left ventricular EDA were unchanged after insufflation. Left ventricular EDA were significantly ($P < 0.05$) reduced after reverse Trendelenburg positioning. LVESWS increased after carbon dioxide insufflation. The increase in LVESWS was statistically significant ($P < 0.05$) 3 min after the insufflation.

A significant linear correlation was observed between MAP and LVESWS before insufflation of carbon dioxide and 3 and 5 min after insufflation and reverse Trendelenburg position ($r = 0.74$, 0.64 and 0.67, respectively). Similarly, significant linear correlations were recorded between the variables MAP and peak airway pressure before carbon dioxide insufflation and 5 min after insufflation and reverse Trendelenburg position ($r = 0.63$ and 0.79, respectively).

DISCUSSION

We found that left ventricular function, as determined by transoesophageal echocardiographic estimation of ejection fraction, was preserved after insufflation of carbon dioxide and changes in patient position, despite variations in loading conditions. However, insufflation of carbon dioxide was associated with increases in left ventricular end-systolic wall stress, concomitant with increases in systemic arterial pressure. In addition, LVEDA decreased after reverse Trendelenburg positioning, while LVEF was maintained. However, it might be speculated that the changes in left ventricular loading conditions might have had deleterious consequences in patients with significant cardiovascular disease.

Laparoscopic cholecystectomy has four potential causes of major physiological changes in the anaesthetized patient—the initial Trendelenburg position, creation of a pneumoperitoneum, the potential for systemic absorption of carbon dioxide, and the reverse Trendelenburg position. Considering the widespread adoption of laparoscopic cholecystectomy, there is a remarkable paucity of data on the haemodynamic and respiratory changes in normal patients and those with cardiorespiratory disorders associated with these manoeuvres. Lack of critical experimental and clinical assessment of the physiological changes associated with laparoscopic cholecystectomy is in marked comparison with data obtained during gynaecological laparoscopy [15, 16].

In laparoscopic procedures, patients are normally placed in a 10–20° Trendelenburg position to keep the small bowel and colon out of the pelvis and to minimize complications associated with blind trocar insertion. Gravity may exert profound effects on the cardiovascular and pulmonary systems. The physiological effects of the Trendelenburg position have been reviewed by Wilcox and Vandam [17]. The associated cardiovascular changes may be influenced by the extent of the head-down tilt, the patient's age, intravascular volume status, associated cardiac disease, anaesthetic drugs and ventilation techniques. However, in our patients, the adoption of the Trendelenburg position was not associated with significant cardiovascular changes, but reverse Trendelenburg positioning was associated with a decrease in indices of left ventricular preload, presumably reflecting a gravitational effect on venous return [18].

The cardiovascular and respiratory changes associated with creation of a pneumoperitoneum have been extensively studied in gynaecological patients. Marshall and colleagues [19] reported no significant changes in cardiac output in anaesthetized, spontaneously breathing patients in whom the intra-abdominal pressure (IAP) was 15–20 cm H_2O (11–15 mm Hg). Smith and colleagues [20] studied the cardiovascular effects of stepwise increases of IAP up to a maximum of 25 cm H_2O in anaesthetized patients undergoing mechanical ventilation. At 25-cm H_2O IAP and increased airway pressure, intrathoracic pressure (ITP), central venous pressure (CVP) and femoral venous pressure were accompanied by hypertension, tachycardia and increased end-tidal carbon dioxide tensions. Based on data obtained from a study of the effects of progressively increasing IAP in horizontal and tilted anaesthetized patients undergoing mechanical ventilation, Kelman and colleagues [21] claimed that moderate increases in IAP (up to 25 cm H_2O) may be accompanied by increased transmural cardiac filling pressure and cardiac output. When IAP was increased further to 40 cm H_2O, tachycardia, hypotension, reduced CVP and cardiac output were observed. These changes were most marked in the horizontal compared with the head-down tilt position. The authors speculated that increased IAP may have two opposite effects on the cardiovascular system—it may force blood out of the abdominal organs and inferior vena cava into the central venous reservoir and may also dam blood back in the legs and thus tend to decrease the central blood volume.

Thus only minor haemodynamic changes occurred during gynaecological laparoscopic procedures with insufflation of carbon dioxide when IAP did not exceed 25 cm H_2O (18 mm Hg). However, these short-duration studies were performed in young, relatively healthy, females in the Trendelenburg position. In our study of older, anaesthetized patients undergoing laparoscopic cholecystectomy, IAP of 15 mm Hg in the reverse Trendelenburg position was associated with increased peak airway pressures, arterial pressure and left ventricular afterload. This study and the limited data available on laparoscopic cholecystectomy suggest that the haemodynamic and respiratory function changes may differ from those reported with gynaecological laparoscopic procedures. In our study, end-tidal carbon dioxide partial pressure increased progressively with time—a finding consistent with data reported by Liu and colleagues [22] and Wittgen and colleagues [23], who demonstrated similar increases in end-tidal carbon dioxide coincident with parallel changes in arterial partial pressures of carbon dioxide during laparoscopic cholecystectomy. Intraoperative hypercapnia may cause increases in plasma catecholamine concentrations, and increases in systemic arterial pressure and cardiac performance [24]. The latter were manifested by a shortened pre-ejection period (PEP), left ventricular ejection time (LVET), and decreased PEP:LVET ratio. Such neurohumoral mechanisms may have contributed to the increases in afterload observed in our study, and the preservation of cardiac performance in the face of these changes.

Systemic arterial pressure was measured using an automated cuff. Such automatic oscillometric measurements have been shown to correlate closely with invasive arterial cannulation and auscultation determinations [25, 26]. End-tidal carbon dioxide tension and oximetry were used as non-invasive substitutes for arterial $P\text{CO}_2$ and $P\text{O}_2$ in evaluating adequacy of ventilation and oxygenation. It is well recognized that end-tidal carbon dioxide partial pressure may differ considerably from Pa_{CO_2} because of ventilation–perfusion mismatching [27]. However, in a study of healthy patients undergoing laparoscopic cholecystectomy, Liu and colleagues [22] observed equal and proportional increases in $P\text{E}'_{\text{CO}_2}$ and Pa_{CO_2} after insufflation of carbon dioxide.

The variables LVEDA, LVEF and LVESWS were measured by transoesophageal echocardiography (TOE). Clements and colleagues [28] and Urbanowitz and colleagues [29] have demonstrated a close correlation between TOE-derived estimates of EDA and LVEF and radionuclide measurements. LVESWS is a quantitative index of left ventricular afterload [13]. In our study, these afterload estimates were based on LV echocardiographic end-systolic diameter (D), wall thickness (WT) and systolic arterial pressure (P), calculated by the formula: $0.334 \times \text{P(D)/WT}\ (1 + \text{WT/D})$ and expressed as dyn cm^{-2}. O'Kelly and colleagues [13] have validated the use of TOE measurements in this context. Quinones and colleagues [14] have reported that LVESWS determinations with arterial pressure cuff systolic pressure measurements correlate closely ($r = 0.97$) with determinations using invasive end-systolic LV micromanometer pressure in patients with chronically sustained hypertension. Reichek and colleagues [30] similarly validated the technique before and after load manipulation with nitroglycerin, nitroprusside, phenylephrine and saline.

It should be noted that our data were obtained in healthy patients. Further studies may be warranted in patients with cardiopulmonary disease.

EFFICACY OF POSTOPERATIVE PAIN TREATMENT REGIMENS USING BOTH BUPRENORPHINE AND PAPAVERETUM SEQUENTIALLY AFTER ABDOMINAL HYSTERECTOMY

D. W. GREEN, L. O'CONNOR AND M. HANNA

SUMMARY

We have undertaken a double-blind, controlled study to test the hypothesis that the efficacy of standard postoperative analgesia by papaveretum or buprenorphine is not compromised by previous or subsequent standard doses of the other agent. After total abdominal hysterectomy under a standardized general anaesthetic, 120 patients (four groups of 30) were allocated randomly to receive, on demand, a single i.v. dose of buprenorphine 0.15 mg or papaveretum 10 mg, followed sequentially by a single dose of i.m. buprenorphine 0.3 mg or papaveretum 20 mg. Three hours after the i.m. dose, all patients received sublingual buprenorphine 0.4 mg. Pain was scored using both a 10-cm horizontal visual analogue scale (VAS) and a nominal scale. Pain intensity differences and patient and nurse satisfaction with the regimens were recorded. Observations were continued for 8 h after operation. The efficacy of papaveretum or buprenorphine was not compromised by previous or subsequent standard doses of the other agent. All four treatment regimens were similarly well tolerated and gave acceptable analgesia in the immediate postoperative period. (Br. J. Anaesth. 1993; **70**: 626–630)

KEY WORDS

Analgesics: buprenorphine, papaveretum. Analgesia: postoperative.

Buprenorphine is a semi-synthetic partial agonist with high affinity at the mu opioid receptor. It is at least 30 times more potent than morphine on a weight-for-weight basis when given by the parenteral route [1]. Although buprenorphine has been shown to be an effective and long acting analgesic by a variety of routes [2–5], its partial agonist profile has led to confusion concerning its use in the postoperative period when it follows, or is followed by, other opioid analgesics [6]. There thus remains the possibility of altered analgesic efficacy if buprenorphine and other mu agonist analgesics, such as papaveretum, are used sequentially in the immediate postoperative period.

The purpose of this study was to test the hypothesis that the efficacy of standard postoperative analgesia by papaveretum or buprenorphine is not compromised by previous or subsequent standard doses of the other agent.

PATIENTS AND METHODS

The study was conducted as a double-blind, parallel group, comparative study of four separate pain treatment regimens based upon the use of both papaveretum (which is the routine in this hospital) and buprenorphine. A research nurse was employed to recruit patients, co-ordinate the study and collect patient data, but was blinded to the individual medication regimen (table I).

We studied 120 female patients aged 18–65 yr and requiring analgesia to alleviate moderate to severe pain after abdominal hysterectomy. Patients were in the weight range 50–90 kg and ASA class I or II. Patients with a history of opioid addiction, current chronic pain management with opioid analgesics for more than 4 weeks, or those who had used opioid analgesics within the previous 7 days were excluded. The study was approved by the local Ethics Committee and conducted in accordance with the Declaration of Helsinki. All subjects gave written, informed consent.

Patients were premedicated with temazepam 20 mg orally, 1 h before the procedure. Anaesthesia was induced with fentanyl 3 $\mu g\ kg^{-1}$ i.v. and propofol 2–3 $mg\ kg^{-1}$ and neuromuscular block produced with vecuronium 0.08 $mg\ kg^{-1}$. The patient's lungs were ventilated with nitrous oxide and 0.5–1 % isoflurane in oxygen and the trachea intubated using a cuffed tracheal tube. During the procedure the lungs were ventilated mechanically and end-tidal carbon dioxide maintained at 4–5 %. Isoflurane 0.5–1 % (end-tidal) was given as required to produce adequate anaesthesia. No further analgesics were given during anaesthesia. Arterial pressure, heart rate and Sp_{O_2} were monitored at 3-min intervals throughout the procedure. After antagonism of residual neuromuscular block with glycopyrronium 5–10 $\mu g\ kg^{-1}$ and neostigmine 20–40 $\mu g\ kg^{-1}$ and return of adequate spontaneous ventilation, the trachea was extubated and the patient returned to the recovery room.

In the immediate postoperative period, when the patient first complained of moderate to severe pain, the first treatment dose was given i.v. The effects of

TABLE I. *Postoperative dose of drugs used in the four regimens*

Group	1st (i.v.)	2nd (i.m.)	3rd (s.l.)
1(a)	Buprenorphine 0.15 mg	Papaveretum 20 mg	Buprenorphine 0.4 mg
1(b)	Papaveretum 10 mg	Papaveretum 20 mg	Buprenorphine 0.4 mg
2(a)	Papaveretum 10 mg	Buprenorphine 0.3 mg	Buprenorphine 0.4 mg
2(b)	Buprenorphine 0.15 mg	Buprenorphine 0.3 mg	Buprenorphine 0.4 mg

the i.v. dose were assessed (see later) at 30-min intervals until the patient requested further analgesia. The second treatment was given on the ward, i.m. on demand and assessment continued for 3 h, at which time the third (sublingual) dose was given. The effects of the sublingual dose were assessed hourly for 4 h or until additional analgesics were required (see below).

No other analgesics, including non-steroidal anti-inflammatory drugs, were administered during the study. If a patient's pain was inadequately controlled by the study medication, she was withdrawn from the study and given suitable alternative treatment.

Prochlorperazine 12.5 mg i.m. was given prophylactically with the second i.m. analgesic dose on the ward, according to our usual practice.

Each individual patient treatment was presented as two sublingual tablets in a polythene bag, with the two ampoules (for i.v. and i.m. injection). The treatments were randomized in numerical order in blocks of four—with one of each treatment regimen per block. The randomization code and all information relating to the drug materials were retained in the hospital pharmacy.

Buprenorphine (Reckitt and Colman) was supplied as ampoules containing 0.3 mg in 1 ml and as 0.2-mg sublingual tablets. Papaveretum (C.P. Pharmaceuticals) was supplied as ampoules containing papaveretum 20 mg in 1 ml. Ampoules for i.v. or i.m. injection were identical.

Patients were assessed by the research nurse for pain intensity using a horizontal, 10-cm visual analogue scale (VAS) [7] where one end of the line represents "no pain" (scoring 0) and the other "worst imaginable pain" (scoring 10). A four-point nominal scale was also used: 0 = no pain; 1 = mild pain; 2 = moderate pain; 3 = severe pain [8]. In addition, patients were assessed for pain relief using the following five-point nominal rating scale: no relief = 0; slight relief = 1; moderate relief = 2; good relief = 3; complete relief = 4. At the end of the study, both the patient's and the nurse's overall impression of the drug regimen was assessed using a five-point nominal scale: very poor = 0; poor = 1; moderate = 2; good = 3; very good = 4. Adverse effects were recorded for the duration of the study period.

Statistical analysis

Age, height and weight were compared between treatment groups using analysis of variance with treatment effects in the model. Compliance with the assumptions was checked by diagnostic residual plots. The patient's race, type of incision used, deviations from standard anaesthesia and any pre-study therapy were compared between treatment groups using Fisher's exact test.

From the pain intensity VAS, the pain intensity difference (PID) was calculated for each patient after the i.m. injection. The VAS assessments of pain intensity at each time within each treatment period were analysed using analysis of variance as above. Pain intensity and pain relief ratings were analysed using extended Mantel–Haenszel tests [9]. For both pain variables, pairwise comparisons were made between treatment groups as appropriate in each treatment period. The number of patients who experienced adverse events in each treatment period were compared using Fisher's exact test. Based on previous estimates of VAS pain scores for sublingual buprenorphine used in postoperative pain, a standard deviation of 3.776 (mean = 4.02) gives a group size of 30 patients (i.e. 120 patients in total) which is sufficient to detect a 30% difference in treatment response at the 5% level of significance with 80% power.

RESULTS

One hundred and twenty patients completed the study. All four groups were comparable in age, height and weight (table II).

Treatment groups 1(a) and 2(b) received buprenorphine and their pain scores were similar, as were those of groups 1(b) and 2(a), who received papaveretum. There were no significant differences between the pain scores (VAS and nominal) on the two treatments (figs 1, 2).

There were no significant differences between groups 2(a) and 2(b), indicating that the effect of i.m. buprenorphine was not dependent on whether or not it was preceded by i.v. buprenorphine or i.v. papaveretum. Similarly, there were no significant differences between groups 1(a) and 1(b), indicating that the effect of i.m. papaveretum did not depend on whether or not it had been preceded by i.v. buprenorphine or i.v. papaveretum (figs 1, 2).

There were no significant differences between i.m. buprenorphine and i.m. papaveretum when they

followed i.v. papaveretum (groups 1(b) and 2(a)), but when they followed i.v. buprenorphine (groups 1(a) and 2(b)), VAS with i.m. papaveretum were significantly smaller ($P < 0.05$) than those with buprenorphine at 1.5, 2 and 3 h after administration (table III).

Patients who had received i.v. buprenorphine had significantly smaller nominal rating scores with i.m. treatment at 30 min and 1.5 h after dose than those who had received i.v. papaveretum (table III).

PID (relief) was recorded in the i.m. treatment phase. For those patients who had previously received i.v. buprenorphine, pain relief from i.m. papaveretum was significantly greater than that from i.m. buprenorphine at 1.5, 2 and 3 h after administration (table III).

All patients received sublingual buprenorphine 3 h after the i.m. injection, so all comparisons are of the effects of the preceding treatments on the sublingual pain scores.

The pre-sublingual pain scores of patients who had received i.m. papaveretum after buprenorphine i.v. were significantly smaller than those of patients who had received i.m. buprenorphine. However, at all subsequent assessment times there were no significant differences between mean pain scores recorded for the four groups.

Both the patients' and nurse's overall assessment of the four treatment groups were similar. The majority (74%) of the patients assessed the study regimens as "good" or "very good". The majority of the nurse assessments were between "moderate" and "good".

There were no serious adverse events (clinically significant respiratory depression or sedation) in any patient during any limb of the study. Eleven patients withdrew before the end of the study period because of insufficient analgesia. There was no significant difference between the numbers of patients withdrawing from each group.

In the i.v. phase, 19 patients (31%) receiving buprenorphine reported 21 adverse events, while 15 patients (23%) receiving papaveretum reported 18 adverse events. These were mainly nausea, vomiting, or both, for both groups, but four patients in the papaveretum group had a cardiovascular event (hypotension or bradycardia). These differences were not statistically significant.

In the i.m. dose phase, five patients (8%) receiving buprenorphine reported six adverse events while 14 patients (22%) receiving papaveretum reported 15 events. Again, these were mostly nausea, vomiting, or both. In the i.m. treatment phase, significantly more patients receiving papaveretum reported an adverse event ($P < 0.005$).

In the sublingual dose phase, 25 patients (20%) reported 31 adverse events.

DISCUSSION

We have shown that the immediate analgesic effect of i.m. papaveretum did not depend on whether or not it had been preceded by i.v. buprenorphine or i.v. papaveretum. Similarly, the immediate effect of i.m. buprenorphine did not depend on whether or not it had been preceded by i.v. papaveretum or i.v. buprenorphine.

The analgesia was similar with both i.m. buprenorphine and i.m. papaveretum after i.v. papaveretum. Those patients transferred to i.m. papaveretum after i.v. buprenorphine had significantly smaller pain scores at 1.5, 2.5 and 3 h after administration than those transferred to i.m. buprenorphine. This is evidence in favour of an additive effect between a partial and a full opioid agonist. Although this effect was not seen in reverse when buprenorphine i.m. followed papaveretum i.v., a previous study showed improved analgesia when sublingual buprenorphine followed intraoperative morphine i.v. [3].

When administered after i.v. buprenorphine, both i.m. buprenorphine and i.m. papaveretum were associated with significantly smaller nominal rating scores at 30 min and 1.5 h than after i.v. papaveretum. This supports the finding that the analgesic effect of papaveretum is not compromised by previous doses of buprenorphine. It may also indicate that the effective analgesia of i.v. buprenorphine is maintained, and possibly added to, on administration of both i.m. treatments.

Buprenorphine has been studied extensively for postoperative analgesia, on its own [4] or in comparison with papaveretum [2], morphine [3], pethidine [5] and pentazocine [10]. It has been shown to be as effective, usually longer acting, and to have side effects similar to those of the other analgesics studied. Effectiveness by the sublingual route, lack of effect on the sphincter of Oddi [11] and minimal controlled drug status [12] confer additional benefits [7].

The analgesic profile of buprenorphine cannot be explained simply by its pharmacokinetics or partial agonist classification. Although the pharmacokinetics of buprenorphine are similar to those of fentanyl, its onset of action is much slower and its duration of action much longer. This difference can be explained by its greater receptor affinity: Boas and Villiger [13] demonstrated 50% receptor dissociation at 1 h for buprenorphine, compared with 100% at 10 min with fentanyl.

Although buprenorphine has been used successfully for sequential analgesia following high-dose fentanyl–sufentanil anaesthesia [14], some have advised against the use of a partial mu opioid agonist in conjunction with a full opioid agonist, either during operation or in the immediate postoperative period [6]. There are three reasons for this concern.

First, there could be displacement of previously administered opioid agonist by the partial agonist, resulting in reduced analgesia. In practice, a high affinity partial agonist, such as buprenorphine, is likely to antagonize the effects of prior administration of agonist only if the latter has been given in excess and is causing severe respiratory depression. In these circumstances, buprenorphine reverses the respiratory depression in a manner similar to naloxone, although analgesia is maintained better with buprenorphine [15].

Second, the effects of a partial agonist given after a full agonist could be additive. Although this may result in enhanced analgesia, it may also cause respiratory depression. In practice, an additive effect of a partial agonist after a full agonist occurs only when the latter is given in moderate dosage, or when the full agonist is exerting a less than optimal analgesic effect. In such circumstances, the effect on analgesia is beneficial [3] and respiratory depression is unlikely to be severe.

Third, if buprenorphine has been used as the primary analgesic, there is concern that it could render subsequent doses of a full agonist less effective because of its extensive mu receptor binding potential and avidity, and its ability to displace the full agonist [13].

In the present study, however, the efficacy of postoperative analgesia with papaveretum or buprenorphine was not compromised by previous or subsequent standard doses of the other agent. All four treatment regimens were similarly well tolerated and gave acceptable analgesia in the postoperative period.

EVALUATION OF THE ANALGESIC EFFECT OF METOCLOPRAMIDE AFTER OPIOID-FREE ANALGESIA

B. LISANDER

SUMMARY

Metoclopramide may enhance opioid analgesia, but it is not known if the drug is analgesic itself. This question was examined in a double-blind, randomized study of 38 patients undergoing knee arthroscopy with opioid-free anaesthesia comprising propofol, isoflurane and nitrous oxide in oxygen. At the end of surgery, patients received either metoclopramide 0.5 mg kg^{-1} or placebo i.v. After operation, they received patient-controlled analgesia with pethidine for 3 h, during which period, pain score was assessed on a visual analogue scale (VAS). There were no significant differences between the groups in the patterns of pethidine consumption. However, the VAS-pain scores tended to be smaller in the metoclopramide group; this difference was significant 30 min after operation. These results do not demonstrate conclusively a clinically relevant analgesic action of metoclopramide. (Br. J. Anaesth. **1993**; **70**: 631–633)

KEY WORDS

Analgesia: postoperative, patient-controlled. Analgesics: metoclopramide.

Clinical studies have reported an analgesic effect of metoclopramide in ureterolithiasis [1], labour [2], termination of pregnancy [3] and prosthetic hip surgery [4]. The mechanisms by which the drug exerts its analgesic action are unknown. In some studies, it enhanced the effect of opioids [2–4]. However, there are reports that metoclopramide is analgesic, even when given alone, in patients [1] and animals [5, 6].

The aim of the present study was to examine if metoclopramide is analgesic by itself in the postoperative situation. The degree of postoperative pain in a study of this type is important: it should not be so severe as to make the majority of patients require supplementary opioid analgesics from the outset, as this would focus the study on the interactive effects of opioids and metoclopramide. Patients undergoing arthroscopy of the knee were considered suitable for this purpose, and no opioids were given during surgery.

PATIENTS AND METHODS

The study was performed in 38 patients undergoing unilateral arthroscopy of the knee in a double-blind, randomized design. Patients with a history of cardiac decompensation, coronary insufficiency, extrapyramidal symptoms, hepatic or gastrointestinal disease or increased serum concentrations of creatinine were excluded. The study was approved by the local Ethics Committee and informed consent was obtained from the patients, all of whom were in ASA group I or II. Before operation, they were instructed about postoperative estimation of pain and the use of patient-controlled analgesia. Triazolam 0.25 mg was given by mouth as premedication 1 h before anaesthesia. Atropine 0.5 mg i.v. was given and general anaesthesia induced with propofol in a dose sufficient to obtund the eyelash reflex. Anaesthesia was maintained with isoflurane and nitrous oxide in oxygen, by spontaneous ventilation via a face mask. The arthroscopies were either diagnostic or were performed for the purpose of partial meniscectomy.

At the end of surgery metoclopramide 0.5 mg kg^{-1} i.v. or placebo was given from coded ampoules containing metoclopramide 100 mg ml^{-1} (Primperan, Lundbeck). The appropriate dose was diluted with 20 ml of saline before use.

After operation, patients were transferred to the postoperative ward. When they could repeat instructions concerning the patient-controlled analgesia (PCA), they were connected to a PCA pump (Prominject Pharmacia) which delivered 10-mg bolus doses of pethidine 10 mg ml^{-1} with a lock-out time of 5 min. After 3 h, the PCA treatment was terminated.

Pain scores were assessed on a visual analogue scale (VAS) (0 mm = no pain; 100 mm = worst pain imaginable) every 30 min during the PCA treatment, starting at 30 min.

Data are presented as median (25–75% range). Statistical analysis was performed with the Mann–Whitney rank sum test or Fisher's exact test. Correction for multiple comparisons (VAS pain scores) was made [7]. $P < 0.05$ was considered statistically significant. For power analysis, a formula for dichotomous values [8] was used.

RESULTS

Nineteen patients received metoclopramide 0.5 mg kg^{-1} i.v. and 19 placebo (control group) (table I).

There were no significant differences between

Preoperative VAS pain score (mm)	0 (0–0)	0 (0–0)
Meniscectomy (No. patients)	9	11
Duration of surgery (min)	20 (15–35)	25 (20–40)
Wake-up time (min)	11 (9–14)	11 (9–15)

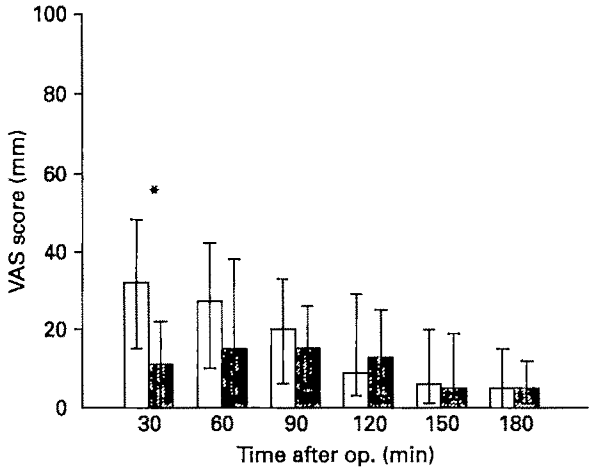

FIG. 1. Postoperative VAS pain scores (median, 25–75% range). □: Placebo (n = 19); ▨: metoclopramide (n = 19). * Significant difference ($P < 0.05$) between groups; at that time, three placebo and five metoclopramide patients had taken PCA pethidine: the difference remained significant after exclusion of these patients.

groups in administration of PCA pethidine. The total dose was 10 (0–10) mg in the metoclopramide group and 10 (0–20) mg in the control group; time to the first dose was 167 (29–∞) min in the metoclopramide group and 70 (45–∞) min in the control group. In the control group, 63% of patients (12 of 19) received PCA pethidine. The study has a power of 80% to detect a decrease in this percentage to 20%. In the metoclopramide group, 53% of patients (10 of 19) received PCA pethidine. Eight patients in the placebo group and three in the metoclopramide group required more than one dose of pethidine.

VAS pain scores (fig. 1) tended to be smaller in the metoclopramide group (significant at 30 min of PCA treatment). Time from the end of surgery (when the study drugs were given) to start of the PCA treatment (when the patients could repeat instructions) was used as a measure of recovery time; no significant difference was noted between groups (table I). Patients receiving metoclopramide were not notably drowsy. No side effects attributable to metoclopramide such as extrapyramidal disturbances, were observed, and emesis was observed in only one patient (receiving placebo and no pethidine).

DISCUSSION

Metoclopramide is a structural analogue of procaine amide, but lacks local anaesthetic and antiarrhythmic activity [9]. Analgesic properties of metoclopramide have been demonstrated in animal experiments and calcium channel- [5], opioid- [5] or prolactin- [6] mediated mechanisms have been suggested.

Clinical studies also have reported analgesic effects of the drug. I.v. metoclopramide 20 mg was at least as effective as atropine 0.5 mg plus morphine 20 mg s.c. in relieving acute pain in ureterolithiasis [1]. I.m. metoclopramide 10 mg enhanced the analgesic effect of pethidine in labour [2]; the same dose i.v. decreased the need for morphine in termination of pregnancy [3]. In all these studies, the analgesic effects were interpreted as mediated by an action of metoclopramide on painful contractions of smooth muscle. However, in a recent study [4] in which patients underwent total hip replacement under intrathecal analgesia supplemented with intrathecal morphine, metoclopramide 1 mg kg^{-1} i.v. followed by an infusion of 1.5 mg kg^{-1} over 9 h decreased the need for postoperative analgesics and prolonged the pain-free time. This suggests that metoclopramide may exert a true analgesic action in the clinical setting.

The mechanism of metoclopramide analgesia remains unknown. The drug antagonizes the 5-hydroxy tryptamine 3 ($5HT_3$) receptor, which is probably the major mechanism of the anti-emetic effect of "high-dose" metoclopramide [10]. Although $5HT_3$ receptor block may be associated with analgesia [11], clinical administration of ondansetron was not shown to decrease the need for postoperative analgesics [12].

Metoclopramide is a potent antagonist of the dopaminergic D_2 receptor [13], accounting for the extrapyramidal side effects of the drug and probably also for its low-dose, anti-emetic effect [10]. Some researchers have suggested that dopaminergic *agonists* increase the efficacy of morphine analgesia, while others have reported an antagonism. These conflicting results may reflect differing degrees of activation of the D_1 and D_2 receptor subtypes [14, 15] or of presynaptic autoreceptors and postsynaptic receptors [16]. While the effects of dopaminergic agonists and antagonists on pain processing are thus insufficiently known, they have frequently been described in terms of enhancement or antagonism of opioid-induced analgesia. There is increasing evidence that such an interaction reflects a functional interconnection between opioid and dopaminergic mechanisms [15].

Even though the D_2-antagonist metoclopramide may enhance opioid analgesia [2–4], analgesic effects of metoclopramide, given alone, have been reported in man [1] and in animals [5, 6]. However, this does not exclude an interaction of the drug with *endogenous* opioid mechanisms.

The aim of the present study was to see if metoclopramide has an analgesic effect in the absence of exogenous opioids. Postoperative PCA consumption of pethidine was chosen as an indicator of an analgesic effect in the expectation that the time to the first dose and the number of patients receiving pethidine after operation would give information on the analgesic properties of metoclopramide *per se*. This was the main objective of the study and it should be noted that the magnitude of the PCA bolus dose and the number of doses after the first one were unimportant in this context. After receiving a first dose of PCA pethidine, the patient could furnish no further information concerning the effect of metoclopramide alone: the number of patients taking more than one dose and the cumulated number of doses in each of these patients describe the interactive effects of metoclopramide and pethidine—a problem for which the study was not designed and regarding which conclusions are not justified. We found no significant differences in postoperative pethidine requirement between patients who received metoclopramide 0.5 mg kg^{-1} and those who received placebo.

The VAS pain scores in figure 1 include observations in patients who had taken PCA pethidine and should therefore be interpreted with caution. However, a trend was observed towards smaller VAS pain scores in the metoclopramide group and this attained statistical significance 30 min after operation, indicating that identical analgesia was not achieved with the PCA treatment. It is now believed commonly that measurement of pain can be accomplished by assessing drug intake during PCA. However, patients utilizing PCA usually do not achieve total analgesia, some fail to obtain adequate relief of pain and significant differences in pain scores have been demonstrated between supposedly comparable groups of patients utilizing PCA [17]. Actual estimations of pain must therefore be accorded due significance. After operation, patients may refrain from utilizing PCA for a variety of reasons, particularly if their pain is tolerable.

There are several possible mechanisms which would explain why the VAS pain scores were markedly less in the metoclopramide group early in the postoperative course but not later. Elimination of metoclopramide is unlikely to have been the cause, as the drug has a terminal half-life of 4.5–8.8 h [18]. The drug may have delayed elimination of the anaesthetic agents and hence depressed nociceptive neurotransmission [19] for example as a result of decreased ventilation; however, the time from the end of surgery to the start of PCA was similar in both groups. More sophisticated measures of recovery are needed before definite conclusions can be drawn in this respect. Even if the rate of elimination of the anaesthetic agents is assumed to have been the same in both groups, metoclopramide may have interacted with residual anaesthetic agents to cause analgesia: common mechanisms of action may exist. For example, changes in neuronal fluxes of the calcium ion are important in producing general anaesthesia and calcium channel antagonists have been reported to increase the potency of drugs such as nitrous oxide, volatile anaesthetics, barbiturates, benzodiazepines and opioids [20, 21]. Metoclopramide analgesia, also, can be potentiated by the calcium channel blocker nifedipine and counteracted by calcium chloride [5].

INCREMENTAL SPINAL ANAESTHESIA FOR ELECTIVE CAESAREAN SECTION: MATERNAL AND FETAL HAEMODYNAMIC EFFECTS

S. C. ROBSON, G. SAMSOON, R. J. BOYS, C. RODECK AND B. MORGAN

SUMMARY

We have performed serial haemodynamic investigations in 20 women undergoing elective Caesarean section under continuous spinal anaesthesia with a 32-gauge catheter with 0.5% heavy bupivacaine. Cardiac output was measured by Doppler and cross-sectional echocardiography at the aortic valve. Doppler flow velocity waveforms were recorded also from the umbilical artery. A block to T4 or above was achieved in all patients. The median dose of 0.5% bupivacaine administered was 2.0 ml (range 1.5–4.5 ml). Mean cardiac output increased from 7 to 8 litre min^{-1} after preloading with Ringer lactate solution 1.5 litre and then remained unchanged after injection of bupivacaine. Two subjects developed hypotension, although mean values of arterial pressure and umbilical artery pulsatility index did not change. The median umbilical artery pH was 7.27 (range 6.98–7.32) and there was a significant correlation between pH and the maximum percentage decrease in cardiac output. The results suggest that continuous spinal anaesthesia is associated with greater haemodynamic stability than single bolus spinal injection. (Br. J. Anaesth. 1993; **70**: 634–638)

KEY WORDS

Anaesthesia: obstetric. Anaesthetic techniques: extradural, spinal. Measurement techniques: Doppler ultrasound, echocardiography. Placenta: umbilical artery flow.

Spinal anaesthesia has several advantages in comparison with extradural anaesthesia for elective Caesarean section; the block is faster and more reliable and, because smaller doses of local anaesthetic are used, the risk of toxicity is reduced [1, 2]. However, decreases in arterial pressure and cardiac output are greater with a single subarachnoid injection and these haemodynamic changes have been associated with alterations in Doppler waveform indices in the umbilical artery and a decrease in umbilical arterial pH at delivery [3, 4].

Spinal anaesthesia using a catheter allows incremental injection of local anaesthetic. This produces a more gradual and predictable block which may be associated with a smaller incidence of hypotension [5]. However, changes in arterial pressure do not accurately reflect changes in maternal cardiac output; indeed, we have shown recently that, unlike changes in maternal cardiac output and umbilical artery Doppler flow velocity waveform indices, changes in arterial pressure do not correlate with umbilical arterial pH at delivery [3]. Although several workers have investigated the haemodynamic changes after single injection spinal anaesthesia, comparable studies have not been performed during incremental spinal anaesthesia.

Cardiac output can be calculated from aortic blood velocity, measured by Doppler ultrasound, combined with aortic orifice cross-sectional area, measured by cross-sectional echocardiography. The technique has been validated in pregnancy [6] and allows reproducible, non-invasive measurements of cardiac output [7]. Doppler ultrasound can also be used to assess the fetal umbilical circulation and flow velocity waveform indices have been shown to be superior to cardiotocography in predicting fetal compromise [8]. We have used these techniques to study maternal and fetal haemodynamic changes during incremental subarachnoid injection of bupivacaine for elective Caesarean section.

PATIENTS AND METHODS

We studied 23 healthy women with a singleton pregnancy admitted for elective Caesarean section at term. Three women were excluded subsequently because of failure to insert the subarachnoid catheter. Details of the remaining 20 subjects are shown in table I. The procedure was explained to each subject and written consent was obtained. The study was approved by the local Ethics Committee.

Each subject received oral ranitidine 150 mg on the evening before and on the morning of the operation. Sodium citrate 0.3 mol litre^{-1} (30 ml) was given on arrival of the patient in the operating theatre. After insertion of an i.v. cannula, Ringer lactate solution 1 litre was infused over approximately 15 min immediately before anaesthesia. With the subject in the left lateral position, a 25-gauge spinal needle (Becton Dickinson) was introduced into the subarachnoid space at the L3–4 intervertebral space. A 32-gauge catheter (Microspinal) was then threaded, via the needle, 3 cm into the

subarachnoid space. One millilitre of 0.5% heavy bupivacaine was injected intrathecally with the mother in the left semi-lateral position. Additional injections of 0.5% heavy bupivacaine 0.5–1.0 ml were given after 5 min and repeated every 3–5 min until a bilateral block from T4 to S5 had been achieved. The block was assessed at 2 min, using the absence of perception of cold sensation to an ethyl chloride spray, and this was repeated every 2 min thereafter until the commencement of surgery. An infusion of Ringer lactate solution 1 litre containing ephedrine 60 mg was commenced immediately after injection of the initial dose of bupivacaine. Thereafter, the rate was determined by the anaesthetist according to the arterial pressure.

Arterial pressure was measured using an automatic non-invasive monitor (Marquette). Measurements of systolic, mean and diastolic pressure were obtained every 2 min. Hypotension was defined as a reduction in systolic pressure of > 20% from the baseline, preanaesthetic value, and was treated by increasing the rate of the ephedrine infusion and, if necessary, additional bolus doses of ephedrine 5–10 mg.

Cardiac output was measured using cross-sectional and Doppler echocardiography. The principles and techniques of aortic flow measurement have been described previously [7]. Briefly, aortic blood velocities were recorded using a 2-MHz continuous wave Doppler transducer (Vingmed) placed in the suprasternal notch. A spectrum analyser performed fast Fourier transform analysis of the Doppler signal and the output was converted to velocity according to the Doppler equation. The angulation of the ultrasound beam was adjusted until the highest velocities with the least spectral dispersion were obtained; these were then stored in the computer memory and it was assumed that the recorded velocities were those at the aortic orifice and that the beam was parallel with flow. Heart rate and systolic velocity integral (area under the velocity curve) were calculated automatically by the computer. For the latter, calculations were made using 15/16 of the maximum frequency in order to exclude high frequency artefacts. The average of eight to 10 consecutive cycles was used for each determination. Systolic aortic orifice diameter was measured in the parasternal long axis plane using a 5-MHz cross-sectional transducer (Ausonics). Measurements were made from the leading edge of the anterior wall to the leading edge of the posterior wall. Diameters from five consecutive beats were averaged and cross-sectional area was calculated from $\pi(D/2)^2$, where D = mean aortic orifice diameter. Cardiac output was calculated from the formula: cardiac output (litre min^{-1}) = stroke volume (ml) × heart rate (beat min^{-1}), where stroke volume = velocity integral (cm) × cross-sectional area (cm^2).

Flow velocity waveforms from the umbilical artery were recorded using a 4-MHz continuous wave transducer linked to the same spectral analyser. Pulsatility index was calculated automatically by the computer using 15/16 of the maximum recorded frequency. The average of three consecutive cycles was used for each determination.

Investigations were performed in the operating theatre with the subject in the left semi-lateral (45°) position. Doppler recordings were completed in 2–3 min and cross-sectional echocardiographic recordings in 1–2 min. Echocardiographic measurements were performed before any intervention, after preloading with Ringer's lactate solution 1 litre and at 5-min intervals after the initial injection of bupivacaine until the time of preparation for surgery. Arterial pressure measurements were continued during the echocardiographic measurements and the mean of two consecutive measurements was used for analysis.

The time between the initial spinal injection of bupivacaine and the start of surgery and the time between the uterine incision and delivery were recorded. At the time of delivery, the umbilical cord was double clamped. Umbilical arterial and venous samples were collected and pH and blood-gas analysis performed within 10 min of delivery of the infant (Radiometer ABL-30). One- and 5-min Apgar scores were assigned by the paediatrician. All subjects had an uncomplicated Caesarean section with a median blood loss of 500 ml (range 300–750 ml).

The haemodynamic results from the 20 subjects having incremental spinal anaesthesia were compared with those from 16 women undergoing elective Caesarean section under standard, single-bolus spinal anaesthesia (mean dose 0.5% bupivacaine 2.2 (SD 0.2) ml). The haemodynamic results in the latter group were obtained using exactly the same methodology; data have been reported previously [3].

Statistical analysis

A repeated measures analysis of variance was performed for each variable using the statistical package BMDP. To overcome the problem of multiple significance testing, the differences between time points were compared using the Studentized range at the 1% level:

$$\text{Range} = q_{(v)} \times (s^2/\sqrt{n})$$

where $q_{(v)}$ = critical value for comparing two time points; s^2 = residual mean square with v degrees of freedom; n = number of subjects. Differences between the incremental and standard spinal groups were compared using Student's t test for normally distributed data and the median test for non-normally distributed data. The association between the change in various haemodynamic variables and umbilical artery pH was assessed by Pearson's correlation coefficient.

RESULTS

The median dose of 0.5 % bupivacaine administered was 2.0 ml (range 1.5–4.5 ml); five subjects required more than 2.5 ml (3.0 ml ($n = 3$), 3.5 ml ($n = 1$), 4.5 ml ($n = 1$)). The number of additional doses required to achieve a block to T4 were: one in four subjects, two in 10 subjects, three in one subject, four in four subjects and five in one subject. A block to T4 or above was achieved by 20 min after the initial injection in 15 subjects (75 %). Upper levels of sensory block achieved were: T4 ($n = 15$); T3 ($n = 2$); T2 ($n = 3$).

Details of operations and neonates are shown in table II. Hypotension occurred in two of 20 subjects (10 %). The umbilical artery pH was < 7.2 in two fetuses (7.19 and 6.98), although in both the 1- and 5-min Apgar scores were normal.

Satisfactory Doppler and cross-sectional recordings were obtained in all subjects. The mean results, together with those of arterial pressure are shown in table III. No patient developed hypotension between the completion of the final haemodynamic recordings and delivery. Because of delay in establishing the block, measurements were continued until 20 min in three subjects and 30 min in one subject; cardiac output and umbilical artery pulsatility index remained stable in each. Systolic, diastolic and mean arterial pressure did not change during the study period. Stroke volume and cardiac output increased after preloading and then returned to basal values at 5 min and 10 min, respectively, after the initial dose of bupivacaine. Thereafter there was no further change. Heart rate was increased at 5 min and remained increased. Fetal heart rate was increased at 15 min. No statistically significant changes were observed in umbilical artery pulsatility index.

subject who subsequently delivered the only acidaemic infant (umbilical artery pH 6.98, base deficit 17.3 mmol litre^{-1}). Interestingly, although the cardiotocograph showed reduced baseline variability after this episode, umbilical artery pulsatility index did not change. Comparative data during standard spinal anaesthesia are shown also in figure 1. The maximum percentage decreases in systolic arterial pressure, mean arterial pressure and cardiac output were greater with the standard spinal technique. There was a significant correlation between umbilical artery pH and the maximum percentage decrease in cardiac output ($r = 0.55$) during incremental spinal anaesthesia, but not with the maximum changes in other haemodynamic measurements.

One subject complained of headache 24 h after operation; she described this as mild, lasting less than 24 h and being relieved by simple analgesics. All the spinal catheters were removed intact. No neurological sequelae were evident in any of the subjects at the time of discharge from hospital.

DISCUSSION

The haemodynamic changes associated with spinal anaesthesia represent the greatest potential hazard of this technique for mother and fetus. The results of the present study show that incremental injection of 0.5% bupivacaine using a spinal microcatheter provided a satisfactory block, with little alteration in maternal arterial pressure and cardiac output. Fetal umbilical arterial flow velocity waveform indices also remained stable during anaesthesia.

Since the completion of this study, reports of cauda equina syndrome associated with the use of small-bore catheters for continuous spinal anaesthesia have led the Food and Drug Administration in the U.S.A. to recall all spinal microcatheters of 27 gauge and smaller [9]. This complication has been reported in 11 patients in whom a small-bore catheter was used to inject 5% lignocaine with 7.5% glucose into the intrathecal space. Because of the potential benefits of continuous spinal anaesthesia and because the potential hazards and means of avoiding them are known, the Department of Health have taken the view that small-bore catheters should continue to be made available for use in the U.K. [10].

Rigler and colleagues [11] reported four cases of cauda equina syndrome in which the dose of local anaesthetic given was greater than that usually administered with a single injection technique. The authors postulated that neurotoxicity resulted from a combination of maldistribution and a relatively large dose of local anaesthetic. Several characteristics of microcatheters may permit maldistribution: the greater resistance reduces the maximum rate of injection and the small size and flexibility may increase the risk of unintentional sacral positioning [11]. Ross, Coda and Heath [12] studied local anaesthetic distribution in a spinal model. They showed that distribution of lignocaine was less uniform and lignocaine concentration in the dependent portions of the model greater after injection through microcatheters compared with a 20-gauge catheter. Wildsmith [13] also drew attention to the possibility of osmotic damage. Although large doses of local anaesthetic have been given during continuous spinal anaesthesia without ill effect [14], it would seem prudent, in view of the probable association with neural damage, to avoid doses far in excess of those given during standard single-injection spinal anaesthesia [15].

Kestin and colleagues [5] compared incremental spinal anaesthesia using a 32-gauge catheter with extradural anaesthesia in women undergoing elective Caesarean section. The spinal catheter was quicker to place and spinal anaesthesia was quicker to establish compared with the extradural technique. Haemodynamic stability and the quality of the block were similar in the two groups. As no previous study had compared haemodynamic changes during continuous and single injection spinal anaesthesia for Caesarean section, we compared the present results with those from 16 previously reported women given a single bolus of 0.5% bupivacaine [3]. Both groups received the same preload and ephedrine regimen and both had identical measurements performed at the same time points. We therefore felt this was an appropriate comparison. Single bolus injection of bupivacaine was associated with greater reductions in arterial pressure and cardiac output. The incidence of hypotension (decrease in systolic pressure > 20%) was also greater in the single bolus group (11 of 16 compared with two of 20 ($P < 0.01$)). These changes were associated with a tendency towards improved umbilical arterial acid–base values in the incremental group (median pH 7.27 (range 6.98–7.32) compared with 7.23 (7.02–7.32) ($P = 0.09$) and base deficit 5.2 (1.8–15.7) mmol litre^{-1} compared with 3.5 (1.7–17.3) mmol litre^{-1} ($P < 0.05$), respectively). Thus continuous spinal anaesthesia was associated with greater haemodynamic stability and a slight improvement in fetal blood-gas tensions.

The median dose of intrathecal bupivacaine administered was 2.0 ml. Kestin and colleagues [5] gave a mean dose of 2.7 ml (range 1.5–7.4 ml) to achieve a similar level of block (T4). We felt that their initial dose (1.5 ml) was too large, as three of 20 women had a sensory block to T3 after this dose. Five women in the present study required more than 2.5 ml of bupivacaine and in each an adequate block was not achieved within 30 min. Kestin's group [5] also reported some patients who needed several increments of bupivacaine: one subject required a total of 7.4 ml. As an alternative to continued administration of the same local anaesthetic, various manoeuvres have been advocated, such as changing patient position, manipulating catheter position and switching to a different local anaesthetic [15, 16]. While the first two of these seem reasonable, there is no evidence to suggest that administration of a second drug is safer than additional doses of the first.

Much attention regarding the use of continuous spinal anaesthesia has been directed at the difficulties encountered inserting the 32-gauge catheter and the risk of postdural puncture headache. Most technical "failures" have been related to catheter kinking [17, 18]. We encountered this problem in three subjects (13%)—a rate consistent with the preliminary experience of other workers [17, 19]. With further experience, the failure rate appears to decrease to < 5 % [5]. Although the present series was small, no subject developed a headache typical of dural puncture. The incidence of postdural puncture headache with spinal catheters has varied from 1 % to 10 % [4, 5]. However, there have been no sizable studies of the use of 32-gauge catheters in obstetric patients to enable the true incidence of postdural puncture headache to be determined.

In conclusion, the results of the present study suggest that continuous spinal anaesthesia combines the reliability of subarachnoid injection and the advantages of repeatability, without the risk of reduction in maternal cardiac output and fetal pH. While these attributes may be valuable in some clinical situations, the advantages must be balanced against the increased cost of technique and the possible risk of neurotoxicity if excessive doses of local anaesthetic are required.

SPREAD OF SPINAL ANAESTHESIA FOR CAESAREAN SECTION IN SINGLETON AND TWIN PREGNANCIES

B. JAWAN, J. H. LEE, Z. K. CHONG AND C. S. CHANG

SUMMARY

We have compared the spread of spinal anaesthesia in parturients with singleton and those with twin pregnancies. Fifty-five unpremedicated patients with uncomplicated pregnancy scheduled for Caesarean section were allocated to two groups: group I = 35 singleton mothers; group II = 20 with twin pregnancy. Both groups received spinal anaesthesia with hyperbaric bupivacaine 10 mg (2 ml of 0.5%). Mean birthweight was 3290 (SD 452) g and 5008 (495) g in groups I and II (combined birthweights), respectively. We found a statistically significant difference in onset and maximal cephalad spread of spinal anaesthesia (group I median T5, range T8–T4; group II T3, range T6–T2). The mechanisms of higher cephalad spread of spinal anaesthesia in parturients may be a decrease in cerebrospinal fluid volume secondary to shunting of blood from the obstructed inferior vena cava to the extradural venous plexus and increased nerve sensitivity to local anaesthetics because of increased concentrations of progesterone. The twin pregnancy group had heavier, larger uteri and greater daily production of progesterone. (Br. J. Anaesth. 1993; **70**: 639–641)

KEY WORDS

Anaesthetic techniques: spinal. Pregnancy: singleton, twins, Caesarean section.

Pregnancy is known to cause higher cephalad spread of spinal analgesia [1, 2]. However, it is not known if there is a difference in the degree of spread between those with twin pregnancy and those with a singleton fetus. This study compared the level of spread of spinal analgesia between these groups of women undergoing elective Caesarean section.

PATIENTS AND METHODS

After obtaining Hospital Ethics Committee approval and written informed consent from the patients, and excluding those parturients with history of hypertension and pre-eclampsia, we studied 55 unpremedicated women, ASA I–II, undergoing elective Caesarean section. Patients were allocated to two groups: group I consisted of 35 parturients with singleton pregnancy; group II, 20 women with twin pregnancy. All patients received spinal anaesthesia, through a 25-gauge disposable needle, comprising 0.5% hyperbaric bupivacaine 10 mg (Marcaine Heavy, Astra) via the L3–4 interspace in left decubitus position. Patients were given lactated Ringer's solution 1000 ml and placed in a supine position with 15° left tilt immediately after the spinal injection. The level of analgesia was checked using pinprick at 2, 4, 10, 14 and 20 min. By 20 min, most of the newborns were delivered. Systemic arterial pressure was measured using an automatic monitor (Dinamap, Criticon) every 5 min. If the systolic AP decreased by more than 20% of the initial value, or to less than 100 mm Hg, ephedrine 12 mg was given i.v. Other variables measured included abdominal circumference and fundus-to-symphisis distance, recorded on admission, and birthweight and placental weight, measured at delivery.

The volume of amniotic fluid was disregarded because accurate measurement was difficult. All data are expressed as mean (range or SD), except for the level of spinal analgesia which is expressed as median (range). Data were analysed using the Mann–Whitney *U* test for the level of spinal spread, unpaired *t* test for parametric data, and chi-square test for the incidence of hypotension. $P < 0.05$ was considered statistically significant.

RESULTS

Parturients with twins were significantly heavier (table I) and had significantly heavier (combined) infant birthweight (5008 (495) g *vs* 3290 (452) g) and placental weight (999 (128) g *vs* 678 (97) g) than those in the singleton group. Abdominal circum-

ference and fundus-to-symphisis distance were also larger in the twin group (table II). The number of patients who needed ephedrine did not differ between groups (57 % *vs* 65 %).

After 10 min, the onset and cephalad spread of spinal analgesia in twin parturients were significantly different than those for singletons ($P < 0.05$) (fig. 1). Spread was to T4 (T10–T3), T4 (T8–T2) and T3 (T6–T2) in the twin group and to T6 (T8–T4), T5 (T8–T4) and T5 (T8–T4) in the singleton group at 10, 14 and 20 min, respectively.

DISCUSSION

We observed that parturients with twin pregnancy had a heavier and larger gravid uterus and more rapid onset and higher cephalad spread of spinal analgesia during Caesarean section compared with those with a singleton pregnancy. Compression of the inferior vena cava (IVC) secondary to increased intra-abdominal pressure has been shown to be an important factor in higher cephalad spread of spinal analgesia [1, 2]—the resulting engorgement of the lumbar and vertebral veins causes a decreased subarachnoid space and smaller CSF volume, and with less spinal fluid present in the subarachnoid space, the same amount of drug causes higher spread inside the narrower space [1, 2]. The fact that CSF volume is an important factor in modifying the spread of spinal analgesia was evident also in our previous study in which, by artificially reducing the CSF volume before administration of spinal anaesthesia, we produced a significant increase in cephalad spread of the spinal block [3].

The incidence of maternal hypotension which required treatment was 20/35 (57 %) in the singleton group and 13/20 (65 %) in the twin group. The supine hypotension syndrome is not related to dose of anaesthetic or the level of spinal anaesthesia [4]. It may be caused by many factors such as occlusion of the IVC, direct compression of the aorta [5, 6], the number of venous collaterals [7], the level of compression [8], low pressure baroreceptors in the vena cava [9], and local sympathetic venoarteriolar reflex [10]. The failure to demonstrate a significant difference between the two groups in the incidence of hypotension does not imply that both groups had the same degree of IVC compression.

The sensitivity of nerve fibres to local anaesthetic agents during pregnancy has been studied extensively [11–13]. In the isolated intact vagus nerve of the pregnant rabbit, sensitivity was increased [12]. Pregnancy also increases peripheral median nerve sensitivity to lignocaine in humans [13]. Increased concentrations of progesterone during pregnancy are thought to be the cause of this increased nerve fibre sensitivity [13, 14]. The CSF concentration of progesterone is increased in parturients and a correlation has been found between the CSF concentration of progesterone and the dose requirement for intrathecal lignocaine [14]. Progesterone in human pregnancy is biosynthesized by syncytiotrophoblasts in the placenta [15]; parturients with twin pregnancy have a heavier placenta and seem to produce more progesterone than those with a singleton pregnancy. Thus nerve fibres in twin gestation may be more susceptible to local anaesthetics.

DIRECT SPINAL EFFECT OF INTRATHECAL AND EXTRADURAL MIDAZOLAM ON VISCERAL NOXIOUS STIMULATION IN RABBITS

M. E. CRAWFORD, F. MOLKE JENSEN, D. B. TOFTDAHL AND J. B. MADSEN

SUMMARY

We measured alterations in a noxious visceromotor reflex in rabbits subjected to intestinal distension, after i.m., extradural or intrathecal injection of midazolam or saline. Spinal catheters were inserted and tunnelled surgically and the animals allowed to recover for 2 weeks. A balloon catheter was placed in the distal part of the descending colon, in the awake rabbit. Intraluminal pressures were increased continuously by water instillation until a sudden withdrawal of the pelvis was observed. Pressure values at withdrawal threshold were recorded immediately before the injection and after 5, 15 and 30 min. Pain thresholds were unaltered after saline. Extradural midazolam 12.5–250 $\mu g\ kg^{-1}$ *produced a dose-dependent increase in the percent maximum possible effect ranging from 7% after the smallest dose to 80%. Similar dose-dependent effects were observed after intrathecal injection of midazolam 25–62.5* $\mu g\ kg^{-1}$. *Extradural and intrathecal, but not i.v. injection of flumazenil 25* $\mu g\ kg^{-1}$ *(a benzodiazepine receptor antagonist) reduced the antinociceptive effect of extradural and intrathecal midazolam to pretreatment levels. A segmental effect of intrathecal midazolam was demonstrated using transcutaneous electrical stimulation in the areas of the neck and the lower back. The effect of intrathecal midazolam 62.5* $\mu g\ kg^{-1}$ *was restricted to the lumbar region, demonstrating a selective action on the spinal cord. Thus extradural and intrathecal midazolam produced a dose-dependent effect on the reflex response to visceral distension in rabbits. This effect is caused by a direct spinal action on benzodiazepine receptors in the spinal cord. (*Br. J. Anaesth. 1993; **70**: 642–646)

KEY WORDS

Anaesthetic techniques: intrathecal, extradural. Pain: visceral, intestinal distension. Pharmacology: midazolam, flumazenil.

Benzodiazepine binding sites are located in the spinal cord [1], with the greatest density of binding sites found within lamina II of the dorsal horn [2]. This region plays an important role in the processing of noxious information. Based on radioligand binding assays and electrophysiological studies, the benzodiazepine binding site appears linked to the $GABA_A$ receptor complex [3].

Benzodiazepines are known to enhance GABA-induced responses of central nervous system neurones *in vitro* [4–6]. Bicuculline, a $GABA_A$ receptor antagonist, has been shown to attenuate the antinociceptive effect of intrathecal midazolam, a water soluble benzodiazepine [7,8]. GABA may play an important role in the modulation of noxious stimuli, as administration of the $GABA_A$ agonist tetrahydro-isoxazolo-pyridinol (THIP) produces antinociception [9]. In addition, midazolam possesses analgesic properties when administered extradurally in humans [10] and intrathecally in rats [8,11–13]. The antinociceptive properties of midazolam appear to be dependent on the type of noxious stimulus used, as it is inactive in the tail flick test [12] and elicits only a weak effect when assessed in the hot-plate tests, in a dose range which lacks additional motor impairment [14].

We evaluated the effect of midazolam, a water soluble benzodiazepine, against visceral noxious stimuli in rabbits and determined if it produced a direct effect on the spinal cord, evaluated by the visceromotor response elicited by intestinal distension.

MATERIALS AND METHODS

The study was approved by the Danish Committee for Animal Research under the Department of Justice and was carried out in accordance with the ethical guidelines for investigation of experimental pain in conscious animals.

Eighteen female New Zealand albino rabbits, body weight 3.5–4.0 kg, were studied.

Catheter implantation

The animals were anaesthetized with a combination of i.m. ketamine 25 mg and xylazine 10 mg, supplemented with 1% lignocaine 5 ml administered s.c. into the area of the skin incision. The skin between L5 and L7 had been shaved previously and disinfected with alcohol. After skin incision the muscular fascia was opened, muscles bluntly detached from the spinous processes and haemostasis obtained by compression. After visualization of the

Correspondence to F.M.J.

ligamentum flavum between the spinous process of L7 and the caudal articular process of L6, a superficial incision was performed in the ligament, and a Portex extradural catheter, o.d. 0.9 mm, inserted and advanced 5 cm cranially. Correct extradural placement produced a rubber-like resistance during insertion. The catheter was secured with a drop of histacrylic glue. The muscular fascia was closed around the catheter and the free end mounted with a detachable Luer lock connector to which a rubber injection membrane had been attached. This end was positioned s.c. and dorsally between the forelegs. The skin was sutured and the animal left for 1–2 weeks; each was in a spacious wooden cage and with free access to food and water.

Intrathecal catheters were inserted using the same procedure except for the incision in the ligamentum flavum. Using a 21-gauge needle, an incision was made through the ligament and dura, resulting in a free flow of cerebrospinal fluid.

Animals presenting any signs of motor dysfunction after catheter implantation were excluded from the study. Cathether position was tested with 1% lignocaine. Injection of 1% lignocaine 0.5 ml extradurally produced weakness of the hindlimbs, whereas 1.5 ml resulted in total paralysis of the same limbs of the extradural batch. Total paralysis was obtained with 0.5 ml of the same solution in all animals of the intrathecal group. Six rabbits had extradural catheters implanted, six had intrathecal catheters and six rabbits were allocated to the group for i.m. injection. One animal in the last group suffered intestinal rupture because of a sudden increase in balloon pressure in the early phase of the study and was excluded and killed immediately.

Tests

The experimental method has been described earlier [15]. In brief, it consisted of a closed circuit containing water. A latex rubber balloon-tipped PVC catheter was used (William Cook, Europe), with an outer diameter of 0.2 cm and a double lumen providing the possibility of simultaneous water infusion and continuous pressure recording inside the balloon. All pressures were measured by a transducer with concomitant paper recording of the pressure curve. A stop-cock and a 20-ml syringe attached allowed a rapid reduction of pressure to 0 after pelvic withdrawal. The balloon catheter was introduced approximately 8 cm into the colon from the anus. Cut-off pressure was set at 100 mm Hg to avoid intestinal rupture.

With a water infusion rate of 15 ml min^{-1}, balloon pressure was increased until a sudden pelvic withdrawal by the rabbit was seen. The maximum intraluminal pressure at the time of this reaction was used to calculate test and control values. This procedure was repeated four times, 30 s apart.

Two investigators performed these measurements: one made the injection, restrained the rabbits loosely during introduction of the balloon, made a note on the recorder of the pressure at which pelvic withdrawal occurred, and emptied the balloon; the other investigator introduced the balloon catheter and observed the rabbit during distension of the balloon. At the time of the visceromotor reflex, this information was passed to the first investigator, who marked it on the recorder. In this way, the experiments were performed blinded to the observer of the visceromotor reflex. Furthermore, this observer was unaware of the drug, dose and route of administration used.

The test and control values were calculated as the mean of the last three measurements, because they had been found in a previous study to be more consistent [15]. In the dose–response study, thresholds were converted for each rabbit to percentage maximum possible effect (%MPE):

$$\%\text{MPE} = \frac{\text{test value} - \text{control value}}{100 - \text{control value}} \times 100$$

where control value = threshold obtained before injection; test value = threshold obtained after drug administration. The cut-off pressure was 100 mm Hg.

Pressure values were recorded before and at 5, 15 and 30 min after intrathecal injections, and at 15 and 30 min for extradural and i.m. injections. The 5-min measurement was avoided in the extradural and i.m. groups in order to allow diffusion of the drugs to the central nervous system. Transcutaneous electrical stimulation was performed via two metal skin electrodes, 2 cm apart. The rabbits were tested in the neck and lower back regions. Electrical energy was applied with a TENS stimulator which provided a constant current over a wide range of skin resistance (Elpha 500, Biometer, DK). Threshold values were defined as the current necessary to produce escape behaviour, expressed in mA, and calculated as the mean of three consecutive measurements.

Drug regimen

The dose–response relationship was assessed utilizing extradural doses of midazolam 250, 125, 25 and 12.5 µg/kg body weight and intrathecal doses of midazolam 62.5 and 25 µg kg^{-1}. I.m. doses were 250 and 62.5 µg kg^{-1}. The extradural doses of midazolam were chosen from pilot experiments preceding this study. The initial intrathecal dose was 25 µg kg^{-1} and increased to 62.5 µg kg^{-1} in order to obtain near maximal effect. The i.m. doses were chosen to correspond to the largest doses of intrathecal and extradural injections.

Drug injections were performed in volumes of 1.5 ml for extradural, 0.5 for intrathecal and 1.0 ml for i.m. injections. Previous studies in our laboratory have shown these volumes to give a distribution of injectate to T4 [16]. All placebo injections consisted of isotonic saline. The benzodiazepine antagonist, flumazenil (Ro 15-1788), was injected into animals in the extradural and intrathecal groups after administration of midazolam in order to evaluate if the effects observed were receptor mediated. Flumazenil injections were either parenteral or spinal (extradural or intrathecal). The dose was 25 µg/kg body weight for both routes of administration. This dose was the largest obtainable with the commercial solution of flumazenil given in a volume of 1 ml and was chosen in order to ensure antagonism of the effects after intrathecal and extradural midazolam.

Statistical methods

Data were analysed using the Wilcoxon rank sum

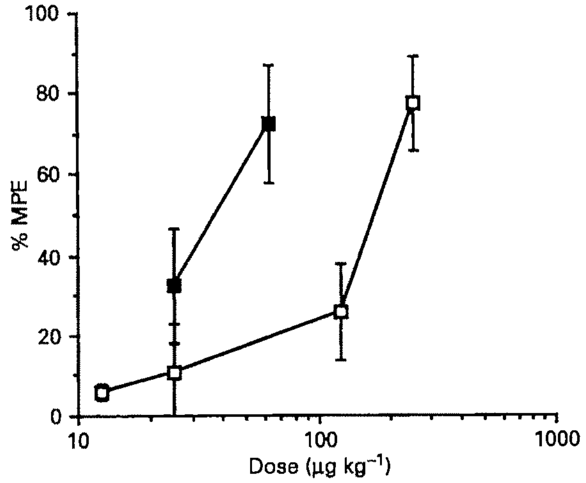

FIG. 1. Dose response 15 min after extradural (□) and intrathecal (■) midazolam: visceromotor reflex (percent of maximal possible effect (% MPE)) elicited by intestinal distension in rabbits. Each point represents mean, SEM; $n = 6$ in both groups.

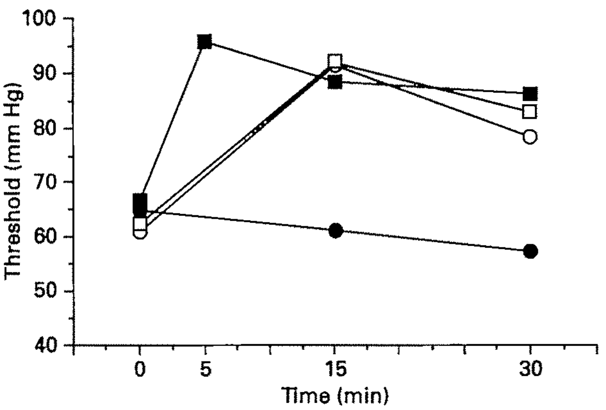

FIG. 2. Increase in intestinal distension thresholds after intrathecal (■) ($n = 6$), extradural (□) ($n = 6$) and i.m. (● = 62.5 μg kg^{-1}; ○ = 250 μg kg^{-1}) ($n = 5$) midazolam. Each point represents mean values. SEM values are omitted for clarity.

test for paired data and Mann–Whitney U test for unpaired data. When more than two groups were compared, the Friedmann two-way ANOVA was used, allowing for multiple testing within the group, when $P < 0.05$. This level of significance was chosen throughout the study.

RESULTS

None of the animals had signs of localized or generalized infection, or signs of motor dysfunction produced by catheter implantation. Body weights were comparable in the three groups.

Extradural or intrathecal injection of lignocaine showed that all catheters were placed correctly.

Saline injections

Injection of isotonic saline 1.5 ml in the extradural and 0.5 ml in the intrathecal group did not produce significant change in threshold to intestinal distension (4.9 (SEM 8.2) % and 0.2 (5.2) % change after extradural and intrathecal saline, respectively).

Extradural administration of midazolam

Extradural midazolam produced a dose-dependent response in the visceral response threshold (fig. 1). The effect of the applied doses was $250 \gg 125 > 25 = 12.5 =$ saline ($P < 0.05$, Wilcoxon rank-sum test, Friedmann test). After the maximal dose of midazolam, there were signs of slight motor impairment in one rabbit, judged by the ability of the animal to walk.

The ability to jump evoked by provocation remained intact. This effect on the motor system lasted for approximately 10 min, thus at the first test 15 min after injection no signs of motor impairment were present. Muscular rigidity was not observed.

Intrathecal administration

The dose–response relationship after midazolam 25 and 62.5 μg kg^{-1} is shown in figure 1. The effect after the large dose was significantly different from placebo at all times (fig. 2), whereas the effect after 25 μg kg^{-1} reached significance only at 5 min after administration (not illustrated). The increase produced by midazolam 62.5 μg kg^{-1} was prolonged and remained stable during the study (fig. 2).

The extradural dose was approximately five times larger than the intrathecal dose required for a 50 % increase in MPE (calculated from figure 1).

I.m. administration

Midazolam 250 μg kg^{-1} produced mean increases in distension thresholds comparable to those observed after extradural administration of the same dose (fig. 2). The smaller dose, 62.5 μg kg^{-1}, produced an insignificant decrease in the distension threshold at 15 and 30 min.

Segmental effect

Using the electrical stimulation test, intrathecal midazolam 62.5 μg kg^{-1} elicited a significant increase in escape threshold in the lumbar region (before: 17.0 (1.3) mA; after 15 min: 21.6 (1.6) mA; 30 min: 21.2 (2.3) mA) ($P < 0.05$), whereas in the cervical region thresholds remained unaltered (9.5, 9.1 and 9.7 mA, before, after 15 and 30 min, respectively) (fig. 3).

Duration of response

The effect was significantly increased throughout the 30-min study period after intrathecal, extradural and the large i.m. dose of midazolam (fig. 2).

Antagonist

After i.v. administration of flumazenil 25 μg kg^{-1}, distension thresholds after extradural and intrathecal midazolam remained virtually unaltered (fig. 4). The same dose of antagonist extradurally and intrathecally not only abolished the response after midazolam administered by the same route (fig. 4), but reduced the distension threshold to less than control values (fig. 4).

Behavioural results

Before each retraction of the pelvis, the rabbit usually showed signs of awareness to the distending stimulus—sitting still, movement of the tail and redness of the ears. These reactions were also observed after administration of midazolam; no other signs of sedation were observed. There were no signs of scratching or biting the lower extremities.

(□) flumazenil 25 $\mu g\ kg^{-1}$ on extradural midazolam 250 $\mu g\ kg^{-1}$ (left) and intrathecal midazolam 62.5 $\mu g\ kg^{-1}$ (right) antinociception against intestinal distension. (In columns ▨, spinal flumazenil was administered by the same route as the midazolam.) ▨ = Midazolam alone. ■ = Values before drug administration (control). $^*P < 0.05$ compared with control.

DISCUSSION

Distension of the colon of the rabbit has been shown to be a reliable and reproducible method of eliciting visceral noxious stimuli in rabbits [15]. This method has been used in several other species, including man, and similar reproducible results were obtained (for review see [17]). The end-point of the test, pelvic withdrawal, depends on normal function of the motor system. In the present study, signs of motor impairment were observed in one rabbit for 10 min (slight dysco-ordination of the hindlimbs during walking, but with an intact ability to jump). At the 15-min time of testing there were no signs of motor impairment. Thus the possible effects on motor function did not occur to any extent after the doses of midazolam used. In a pilot study performed to determine the dose range for the present study, extradural midazolam 1000 $\mu g\ kg^{-1}$ produced a flaccid paralysis of the hindlimbs for approximately 1 h in all rabbits. This dose is four times the maximum dose used in this study and these results are in accordance with the results obtained by Yanez and co-workers [14], who also observed paralysis in rats given approximately six times the antinociceptive dose of midazolam.

A receptor link between the $GABA_A$ site and the benzodiazepine site in the spinal cord has been described earlier [3]. Recent work by Edwards and co-workers [8] confirmed this linkage. They found that bicuculline, a $GABA_A$ receptor antagonist, was able to attenuate the effect of spinally administered midazolam.

This fact, combined with the antinociceptive effect after intrathecal administration of THIP, a specific $GABA_A$ agonist [9], supports a physiological and an anatomical link between the two receptors. This link may also be responsible for the motor effects observed after larger doses of intrathecal and extradural midazolam. The existence of GABA receptors on motor neurone membranes in combination with a link with the benzodiazepine receptor explains the antispastic effect of benzodiazepines.

In the present study, extradurally and intrathecally administered midazolam produced a dose-dependent, pronounced effect against visceral noxious stimulation. The apparently increased potency after intrathecal compared with extradural midazolam is in accordance with experience from human studies, in which morphine 0.5 mg intrathecally appeared equianalgesic with extradural morphine 2–4 mg.

The effects of midazolam were antagonized by the benzodiazepine antagonist flumazenil, but only after concomitant extradural or intrathecal administration and not by i.v. administration. These observations, in combination with the greater efficacy following intrathecal administration of midazolam and the segmental analgesia obtained in the electrical stimulation test, strongly suggest a selective spinal action of extradural and intrathecal midazolam. Furthermore, if the antagonist action of intrathecal and extradural flumazenil were caused by a central distribution to the brain, one would expect parenteral administration of flumazenil to exert at least some degree of antagonism against both intrathecal and extradural midazolam. The direct spinal action of midazolam has been confirmed in previous studies [8,12,13].

The antinociceptive effect after the largest i.m. midazolam dose, 0.25 $mg\ kg^{-1}$, could be mediated via a local action on the spinal cord, as midazolam penetrates the blood–brain barrier easily. The reduction in thresholds after parenteral injection of a small dose of midazolam (62.5 $\mu g\ kg^{-1}$) supports this hypothesis and is in accordance with the work by Daghero, Bradley and Kissin [18]. They found that small doses of midazolam in the spinal cord produced analgesia, whereas small doses in the brain produced hyperalgesia. The hypothesis by Fields, Heinricher and Mason [19] concerning on- and off-cells in the rostral ventromedial medulla (RVM) exerting a descending control of noxious stimuli at the level of the spinal cord and the inhibition of off-cells by GABA resulting in hyperalgesia, is in accordance with present and previous observations of various effects after benzodiazepines: they are able to attenuate opioid-induced antinociception [20] and produce hyperalgesia when administered parenterally or in the brain, but elicit antinociception when they are administered locally at the spinal cord.

The reduction in distension thresholds to less than control values obtained by intrathecal administration of flumazenil $25\ \mu g\ kg^{-1}$ could implicate a tonic active GABA–benzodiazepine system in the modulation af visceral pain. This hypothesis is supported by the work of Edwards and co-workers [8], who found that bicuculline, a $GABA_A$ antagonist, produced hyperalgesia together with allodynia, when given intrathecally in rats. Ness and Gebhart [21] have recently discovered the existence of a descending inhibitory system of neurones in the spinal cord, which are excited by colorectal distension. The inhibition originated from areas in both the periaqueductal grey matter and the RVM.

The effect after intrathecal midazolam appears to be dependent on both the nociceptive test used and the choice of species. Yanez and co-workers [14] found morphine to be approximately 15 times as effective as midazolam on a molar basis, when using the hot-plate test in rats. Serrao and co-workers [13] found fentanyl was only five times as effective as midazolam against electrical stimulation in rats, whereas they found no effect of midazolam on the tail-flick response. The present results compared with unpublished data from our laboratory reveal midazolam to be approximately 20 times as effective as morphine against intestinal distension in rabbits. These differences in effect after morphine and midazolam on different noxious stimuli are physiological evidence of the anatomical separation of intraspinal pathways of visceral and somatic afferent fibres [22,23]. The results obtained in this study have not confirmed those of a preliminary study in humans [24], in which different doses of intrathecal midazolam were found to be effective against per- and postoperative somatic pain and ineffective against sympathetic reflexes produced by manipulation of abdominal contents and against postoperative pain of assumed visceral origin. The preliminary nature of this study, the differences in methods of visceral stimulation and the different species studied make comparison impossible, but point to the need for further studies in humans to determine the effects of spinally applied midazolam on different types of visceral pain.

ACKNOWLEDGEMENTS

This study was financed with a grant from Hoffmann–la Roche, Copenhagen. We thank Birgit O. Mikkelsen, M.SC., of Hoffmann–la Roche for theoretical support and for supplying the test drugs, Professor Tony L. Yaksh for constructive criticism and Peter Urban for assistance. William Cook, Europe, produced the balloon catheters.

CARDIOVASCULAR EFFECTS OF I.V. INDUCTION IN CHILDREN: COMPARISON BETWEEN PROPOFOL AND THIOPENTONE

C. S. T. AUN, R. Y. T. SUNG, M. E. O'MEARA, T. G. SHORT AND T. E. OH

SUMMARY

We have compared the haemodynamic responses to i.v. propofol 2.5 mg kg^{-1} with those to thiopentone 5.0 mg kg^{-1} in 41 healthy Chinese children at induction of anaesthesia. They were allocated to four groups according to their age and induction agent received: group I < 2 yr, propofol, n = 9; group II < 2 yr, thiopentone, n = 9; group III 2–12 yr, propofol, n = 12; group IV 2–12 yr, thiopentone, n = 11. Anaesthesia was maintained by spontaneous ventilation with 70% nitrous oxide and 0.5% halothane in oxygen. Arterial pressure and heart rate were monitored by automatic oscillotonometer. Stroke volume was measured by two-dimensional echocardiography and pulse Doppler. Measurements were made before induction and at 1-min intervals for 5 min after induction. The reduction in mean arterial pressure was significantly greater after propofol (28–31%) than after thiopentone (14–21%) (P = 0.001). The reduction in cardiac index (10–15%) after induction was not significantly different between the two agents (P = 0.122). Baroreflex mediated increases in heart rate and systemic vascular resistance were less after propofol than after thiopentone. The baroreceptor reflex was more attenuated in children aged less than 2 yr than in older children. (Br. J. Anaesth. 1993; **70**: 647–653)

KEY WORDS

Anaesthetics: intravenous, propofol, thiopentone. Anaesthesia: paediatric. Heart: cardiac output. Measurement techniques: echocardiography.

Induction of anaesthesia with propofol is associated with a significantly greater reduction in arterial pressure than with thiopentone, both in adults [1–4] and in children [5–7]. This is one of the main criticisms of the use of propofol. In adults, the mechanism of hypotension has been studied by the invasive thermodilution method [2, 4, 8, 9]. The primary mechanism appears to be a reduction in systemic vascular resistance. There is controversy about its direct cardiovascular effects. However, it appears to exert a mild negative inotropic effect. Because of ethical and technical constraints, haemodynamic data in children are limited to non-invasive measurements of heart rate and arterial pressures [5–7], but these peripheral haemodynamic measurements are inadequate to describe the myocardial effects of anaesthetic agents [10]. With the development of echocardiography it is now possible to measure cardiac output non-invasively with accuracy by combining the technology of echocardiography and the Doppler principle. Measurement of cardiac output using the technique of pulsed Doppler echocardiography has been shown to have a high correlation coefficient ($r = 0.90–0.98$) compared with the dye dilution technique [11, 12]. In this study, this technique was used to compare the cardiovascular effects of i.v. induction of anaesthesia with either propofol or thiopentone in Chinese children.

PATIENTS AND METHODS

The study was approved by the Clinical Research Ethics Committee of the Chinese University of Hong Kong. We studied 45 healthy Chinese children aged between 8 months and 12 yr (ASA I or II) scheduled for elective surgery. Informed consent was obtained from their parents. Children with a history of allergy, or of any adverse reactions to previous anaesthetics were excluded. Those children in whom pre-induction haemodynamic variables or venous cannulation could not be obtained were withdrawn from the study. All patients were premedicated with oral diazepam syrup 0.4 mg kg^{-1} and EMLA cream (lignocaine 25 mg g^{-1} and prilocaine 25 mg g^{-1}, Astra pharmaceuticals, Sweden) applied to the dorsum of both hands approximately 2 h before anaesthesia. The children were grouped into two age groups: less than 2 yr and between 2 and 12 yr. Children in each age group were allocated randomly in a double-blind manner to receive either propofol 2.5 mg kg^{-1} or thiopentone 5 mg kg^{-1}.

On arrival in the anaesthetic room, a non-invasive automatic pressure monitor (Dinamap 845 XT,

Critikon Inc., Florida, U.S.A.) was applied to one arm, and a 24-gauge cannula was inserted into a vein in the opposite hand, where an oximeter probe (Satlite, Datex Instrumentarium Corp., Helsinki, Finland) was attached for continuous monitoring of arterial oxygen saturation. The child was allowed to settle and baseline haemodynamic measurements obtained. The child was noted to be either calm or agitated at this stage. After baseline recordings, the appropriate i.v. agent was injected over a period of 20 s. One percent lignocaine 0.05 ml was added to each 1 ml of propofol immediately before administration. As soon as the child was asleep, a face mask was applied and anaesthesia maintained with 70% nitrous oxide and 0.5% halothane in oxygen using a Jackson–Rees modified Ayre's T piece. Haemodynamic variables were monitored at 1-min intervals for 5 min from the end of i.v. injection. End-tidal carbon dioxide concentration was monitored using a mainstream capnometer (HP 78356A, Hewlett–Packard, California, U.S.A.) attached to the face mask. Fresh gas flow was adjusted and ventilation assisted if necessary to maintain end-tidal carbon dioxide concentration at 4.7–6.0 kPa.

Arterial pressure and heart rate were recorded by the Dinamap. Stroke volume was obtained by an ultrasound scanning device (Aloka-280, Aloka Co., Ltd., Tokyo, Japan) using a handheld Doppler probe of 5 MHz. An initial two-dimensional echocardiogram was scanned along the parasternal longitudinal axis to obtain the internal aortic diameter at the aortic annulus. Three measurements were performed and the average was taken as the aortic diameter. Pulsed-wave Doppler signals from the ascending aorta were identified and recorded by placing the transducer probe at the suprasternal notch. The transducer was positioned to align the transmitted sound beam as parallel as possible to the velocity vector of the blood flow. All the computations were performed by the built-in program of the ultrasound scanner. The Doppler recordings and ECG tracings were recorded on videotape and analysed at a later time.

The velocity of the blood flow was calculated by the Doppler equation:

$$V = \Delta fc/2fo$$

Any deviation of the transducer from the parallel axis of more than 20° angle was corrected by the formula:

$$V = \Delta fc/2fo \operatorname{Cos}\theta$$

where V = velocity of blood flow; Δf = change in frequency; c = sound velocity in the blood; fo = transmitting frequency; θ = angle of insonance or the angle between the beam of ultrasound and the direction of blood flow.

Stroke volume (SV) was computed by multiplying the average time velocity integral by aortic cross-sectional area using the formula:

$$\mathrm{SV} = \mathrm{CSA} \sum_{t=0}^{t=\mathrm{ET}} V\Delta t$$

where CSA = cross sectional area of aorta, V = velocity, t = sampling interval, ET = ejection time.

The stroke volume was calculated by averaging the measurements obtained from three consecutive cardiac cycles. All Doppler recordings and measurements were performed by a single observer (R.Y.T.S.), who was blind to the medication given.

Derived haemodynamic variables calculated from the measured variables included cardiac output, stroke volume index and cardiac index. Cardiac output was calculated as the product of stroke volume and heart rate. Surface area was derived from a nomogram for infants and children [13]. Systemic vascular resistance (SVR) was calculated using the following formula [14]:

$$\mathrm{SVR}\ (\mathrm{dyn\ s\ cm^{-5}}) = \frac{\text{mean arterial pressure}}{\text{cardiac output}} \times 80$$

In order to compare the effects of two agents in two age groups of children, the patients were allocated to four groups:

group I: toddlers younger than 2 yr who received propofol;

group II: toddlers younger than 2 yr who received thiopentone;

group III: children aged 2–12 yr who received propofol;

group IV: children aged 2–12 yr who received thiopentone.

Patient data between the same age groups were compared using a two-tailed Student's t test. The number of agitated children and the incidence of side effects were analysed by chi-square test. The baseline haemodynamic variables were compared by one-way analysis of variance. The haemodynamic measurements after induction were analysed using repeated measures analysis of variance for the difference from the baseline values. The factors included were time after induction, anaesthetic agents and age interaction. In the absence of statistically significant age-by-anaesthetic agent interactions, data from the four groups were compared simultaneously in the results. $P < 0.05$ was considered as statistically significant.

RESULTS

Four cases were excluded from the analysis because of inadequate Doppler recordings. Of the 41 patients studied, 18 were toddlers (nine in group I, nine in group II), and 23 were older children (12 in group III and 11 in group IV). Patient data and the ratio of agitated to calm children in each group are listed in table I. There were no statistically significant differences in mean age, body weight and surface area between groups I and II or between groups III and IV. In groups III and IV, there were more girls. There were more anxious children ($P = 0.01$) in groups I and II when compared with groups III and IV (table I).

Baseline haemodynamic variables were not significantly different between groups I and II or between groups III and IV (table II). The mean heart rates were greater ($P = 0.001$) and systemic vascular resistance values greater ($P = 0.003$) in the toddlers (groups I and II) than their respective values in the

older children (groups III and IV). The differences in arterial pressures, systemic vascular resistance and cardiac index among the four groups were not statistically significant.

After induction, systolic, mean and diastolic arterial pressures decreased significantly ($P < 0.001$) in all four groups (fig. 1). In the toddlers, the maximum reduction in mean arterial pressure was 31% after propofol (group I) and 21% after thiopentone (group II). In the older children, the maximum reductions were 28% after propofol (group III) and 14% after thiopentone (group IV). For both age groups, the differences were significantly more after propofol than after thiopentone ($P = 0.011$).

Heart rate decreased significantly in toddlers who received propofol (24%); the decrease was significantly more than for those who received thiopentone (11%) ($P = 0.024$). The mean heart rate was stable in the older children who received either propofol

(group III) or thiopentone (group IV) (fig. 1). There was a significant difference ($P < 0.001$) in the magnitude of heart rate changes for the two age groups.

There was an increase in stroke volume index after induction up to a maximum of 12% in the toddlers both after propofol (group I) and after thiopentone (group II). In the older children, stroke volume index decreased maximally by 13% after propofol (group III) and 15% after thiopentone (group IV). These changes were not statistically different (fig. 2).

Cardiac index, which is a reflection of the combined effects of heart rate and systemic vascular resistance, decreased significantly ($P = 0.005$) in all four groups (fig. 2). In the toddlers, the maximum decrease in cardiac index was 15% after propofol and 3% after thiopentone. In the older children, the maximum reduction was similar (10%) after each agent.

Systemic vascular resistance decreased significantly ($P = 0.001$) after induction in all four groups (fig. 2). The maximum reduction was similar for the toddlers who received propofol (15%) and those who received thiopentone (16%). The decrease in systemic vascular resistance in older children who received propofol was almost three times as much (19%) as the reduction in children after thiopentone (7%). The differences between the four groups were not significant.

None of the children showed signs of wakening during the study period. There were no differences between the groups in the incidence of side effects (table III).

DISCUSSION

We have shown that i.v. induction of anaesthesia in children using propofol was associated with more cardiovascular depression than an equipotent dose (see below) of thiopentone. The degree of cardiovascular depression in toddlers was similar to that in older children.

This study used the non-invasive technique of pulsed Doppler and two-dimensional echocardiography to determine the stroke volume and cardiac output. The measurements are highly reproducible [11, 15] and can accurately detect relative cardiac output changes in individual patients. It has been shown to correlate well with thermodilution and dye dilution outputs in infants and young children [12, 15, 16]. Determination of cardiac output using M-mode echocardiography calculates volume from a measurement in a single dimension, and therefore any error made during the measurement could be magnified in the subsequent calculations [17]. M-mode identifies the aortic root area only during valve motion, whereas two-dimensional echocardiography can identify both aortic annulus (orifice) and root area. Aortic annulus diameter does not change during systole and therefore calculation of cardiac output using measurement at this site agrees more closely with invasive techniques than using aortic root measurements. Pulsed Doppler has been suggested to be a better technique than continuous Doppler. Pulsed Doppler permits measurement of flow velocity by range-gating at the specified location of the aortic orifice, whereas continuous wave Doppler measures velocity along the entire beam path and may include an area with a parabolic velocity profile which may give a misleading mean spatial velocity [12].

Equipotent doses are required for comparison of cardiovascular responses between two agents. We chose the dose of thiopentone 5 mg kg^{-1} as being equipotent with propofol 2.5 mg kg^{-1}. This ratio was based on previous work on their relative potencies [18, 19].

To our knowledge, no previous study has compared in children the cardiovascular effects of propofol and thiopentone during induction of anaesthesia. In this study we found that mean arterial pressure reduction after propofol was significantly greater than after thiopentone in both toddlers and older children ($P = 0.011$). This is similar to the finding in adults that propofol is more depressant on the cardiovascular system than thiopentone [2, 4]. Our magnitude of arterial pressure reduction after propofol was similar to that found in previous studies [7, 20, 21].

In healthy adults, thiopentone characteristically produces a reduction in arterial pressure and cardiac output, with or without a compensatory increase in total systemic vascular resistance [22–24] and a decrease in baroreflex sensitivity, associated with tachycardia [25]. The cardiovascular depression caused by thiopentone is caused by a combination of depression of the vasomotor centre [26] and direct myocardial depression [27, 28]. Venodilatation leading to a sequestration of blood volume in the venous side of the circulation and a reduction in the left ventricular diastolic filling and stroke volume have also been suggested [29]. The effect on arterial resistance vessels is variable as demonstrated by the inconsistent changes in systemic vascular resistance with barbiturates.

The children receiving thiopentone in our study had a significant reduction in arterial pressure and cardiac index. However, systemic vascular resistance decreased rather than increased. The changes in heart rate were different between the two age groups. Mean heart rate increased in the older children, but decreased in the toddlers (fig. 1). A comparative study of thiopentone in infants and children, observed a greater degree of myocardial depression than that in the present study [30], probably because of the larger dose of thiopentone (7.5–8.5 mg kg^{-1}) in that study.

Studies of the mechanism of propofol-induced hypotension in adults have produced conflicting results [31]. Lippmann and colleagues, using the thermodilution technique, observed a reduction in left ventricle stroke work index (35 %) and cardiac index (18 %), with no significant decrease in systemic vascular resistance and pulmonary vascular resistance [4]. Gauss and co-workers, using echocardiographic assessment and end-systolic quotient as an indicator of inotropy, found that propofol induced hypotension as a result of simultaneous negative inotropy and reduction in afterload [32]. Grounds and colleagues, using the thermodilution technique, observed a significant decrease in total systemic vascular resistance (18 %) with minimal changes in heart rate and cardiac output [2].

In this study, the magnitude of hypotension after propofol was similar to that found in adults [2]. It was associated with a significant reduction in both cardiac index (10–15 %) and systemic vascular resistance (15–19 %). Heart rate in the older children did not change, but it decreased significantly in the toddlers (fig. 1). More toddlers were crying on arrival in the operating theatre than among older children and this may have caused an increase in sympathetic tone. We suspect this was reflected in their greater heart rates and systemic vascular resistance. Anaesthesia attenuates sympathetic tone and this may have contributed to the greater reduction in heart rate in the toddlers. However, heart rates were all within the physiological range (fig. 2). Baroreceptor reflexes have been found to be more attenuated in both young animals and humans anaesthetized with halothane [33, 34] or nitrous oxide [35] compared with adults. It is possible, therefore, that the difference in reduction in heart rate was a reflection of a more significant baroreceptor impairment in the toddlers than in the older children. When comparing the two agents, the decrease in heart rate after propofol was greater than after thiopentone. This suggests that propofol causes more baroreflex depression than thiopentone, in agreement with previous studies in adult patients [36, 37].

Paediatric patients are thought to have a limited ability to increase myocardial contractility and heart rate is an important factor in determining cardiac output [38]. However, the toddlers in this study had an increase rather than a decrease in stroke volume index associated with the reduction in heart rate. This suggests that the myocardium is capable of increasing stroke volume in this age group. Ventricular diastolic filling time and stroke volume are inversely proportional to baroreceptor reflex-mediated changes in heart rate. The net effect of these haemodynamic responses was to produce a non-significant difference in the reduction of cardiac index in all four groups. Like thiopentone, there was no compensatory increase in systemic vascular resistance after propofol.

Diazepam premedication was necessary to reduce anxiety and allow baseline haemodynamic measurements. We used a dose of 0.4 mg kg^{-1} because, with smaller doses, excitement may occur from a lack of inhibition [39]. Its use as premedication is not associated with significant cardiovascular depression [40]. Any incidental haemodynamic effects caused by the premedication should be considered as relevant to the use of these induction agents in the clinical setting.

ACKNOWLEDGEMENT

We wish to thank Dr D. Y. H. Leung, the Faculty Statistician for his assistance with the statistical analysis of the data.

EFFECT OF EXTRADURAL ANALGESIA ON STRESS RESPONSES TO ABDOMINAL SURGERY IN INFANTS†

A. R. WOLF, R. L. EYRES, P. C. LAUSSEN, J. EDWARDS, I. J. STANLEY, P. ROWE AND L. SIMON

SUMMARY

We studied 40 children younger than 4 yr having elective abdominal surgery under general anaesthesia supplemented with either systemic opioids or extradural bupivacaine. Venous blood samples were obtained before tracheal intubation to measure baseline concentrations of adrenaline, noradrenaline, glucose, ACTH and cortisol. Additional samples were obtained 45 min after the start of surgery, at the end of surgery, 1 h and 24 h after the end of surgery. Plasma concentrations of bupivacaine were measured also in the extradural group at each sampling time. Both techniques provided acceptable analgesia, but the perioperative increases in adrenaline, glucose and ACTH were significantly greater in the opioid group. Noradrenaline concentrations decreased to less than baseline values in the extradural group and were significantly less than in the opioid group. The perioperative increase in cortisol was similar in the two groups, despite the differences in ACTH responses. Most responses returned to the baseline values within 24 h. Plasma bupivacaine concentrations remained within safe limits during the study, but systemic concentrations increased in some of the patients during postoperative infusion with 0.125% bupivacaine. (Br. J. Anaesth. 1993; **70**: 654–660)

KEY WORDS

Anaesthesia: paediatric. Anaesthetic techniques: extradural, caudal. Metabolism: stress response.

Studies on newborn infants have demonstrated that inadequate analgesia or anaesthesia may result in a massive stress response and that analgesic drugs which modify the response can be beneficial to postoperative recovery [1, 2]. Unfortunately, effective ablation of the stress response to major surgery requires doses of opioids far greater than are needed to provide analgesia, and necessitates postoperative ventilation [3]. This is impractical for most infant surgery and opioids are limited usually to doses which allow immediate postoperative extubation.

In adults, extradural bupivacaine can suppress stress responses to pelvic and lower limb surgery more effectively than conventional analgesic doses of systemic opioids [4, 5]. However, responses to upper abdominal surgery remain marked even when analgesic combinations of extradural bupivacaine, systemic morphine and indomethacin are used [6]. In children, lumbar extradural and caudal blocks with local anaesthetics can abolish or reduce the increase in cortisol and catecholamines in response to inguinal herniorrhaphy, orchidopexy and hypospadias repair [7, 8], but there are no data on the effect of extradural techniques on stress responses in infants undergoing major abdominal surgery.

We have measured the blood concentrations of adrenaline, noradrenaline, glucose, ACTH and cortisol in infants having abdominal surgery under general anaesthesia supplemented with either extradural bupivacaine or systemic opioids. We hypothesized that extradural analgesia would suppress stress responses to abdominal surgery to a greater extent than opioid analgesia even when both groups received dosage adequate to produce postoperative analgesia.

PATIENTS AND METHODS

The investigation was approved by the Ethics Committee at the Royal Children's Hospital in Melbourne. Informed parental consent was obtained to study 40 infants younger than 4 yr, undergoing elective abdominal surgery. Patients with known endocrine or neurological abnormalities and those with conditions likely to alter stress hormones (such as pain or hypovolaemia) were excluded from study.

Patients older than 4 months received premedication with trimeprazine syrup 1.5 mg kg^{-1} 1 h before surgery. On arrival in the operating room, baseline arterial pressure and heart rate were measured. Anaesthesia was induced with nitrous oxide and halothane in oxygen, and an i.v. cannula was inserted to obtain baseline blood samples before intubation. The cannula was heparinized and remained dedicated for subsequent venous blood

samples. Vecuronium was given via a second i.v. cannula placed in another limb, to facilitate tracheal intubation. Fluid maintenance comprised Ringer's lactate solution in a standardized fashion (4 ml kg^{-1} h^{-1} for subjects weighing up to 10 kg and an additional 2 ml kg^{-1} h^{-1} in those heavier than 10 kg). Additional losses were replaced with Ringer's lactate or blood products according to clinical requirements. Anaesthesia was maintained with 70 % nitrous oxide and 0.5–1 % halothane in oxygen. Arterial pressure and heart rate were recorded at 5-min intervals throughout surgery.

Patients were allocated randomly to receive either i.v. opioids or extradural bupivacaine during and after surgery. Patients in the opioid group were given fentanyl 1 μg kg^{-1} before surgical incision. Additional doses of 0.5 μg kg^{-1} were administered if systolic arterial pressure or heart rate increased to 20 % greater than baseline. Halothane concentration was increased temporarily to a maximum of 1 % during episodes of hypertension and tachycardia while the fentanyl was taking effect. Patients in the extradural group were turned on their side and an extradural cannula was inserted via either the caudal or lumbar route according to clinical preference, using a Portex minipack system (ref: 100/391/091) which provides a 22-gauge extradural catheter. The catheters were inserted in a rostral direction to a distance calculated to leave the tip at a position appropriate for the proposed surgery (the upper lumbar region for lower abdominal surgery and the mid thoracic region for upper abdominal surgery). An initial dose of 0.25 % plain bupivacaine 1 ml was given after insertion of the catheter, and subsequent dosing with 0.25 % bupivacaine was based on the same haemodynamic criteria as for the fentanyl group. The total volume was limited to 1 ml kg^{-1} (bupivacaine 2.5 mg kg^{-1}) during surgery to avoid systemic overdosing.

After surgery, the patients remained in a recovery area for 1 h before discharge to the regular ward. Nursing staff evaluated pain in the recovery area, and on the ward, using a simple scoring system: 0 = asleep; 1 = no pain (awake and calm); 2 = mild pain (crying but able to be comforted); 3 = moderate to severe pain requiring additional analgesia (agitated, crying and not able to be comforted). Morphine was used for postoperative analgesia in the opioid group and nursing staff were allowed to administer a loading dose of morphine 10–50 μg kg^{-1}, to ensure that each patient had adequate analgesia (pain scores of 0, 1 or 2) in the recovery area. An infusion was commenced at an initial rate of 10–20 μg kg^{-1} h^{-1}, and modified up to a maximum of 50 μg kg^{-1} h^{-1} according to 4-hourly pain observations. Incremental doses of 50 μg kg^{-1} were also permitted as necessary to maintain good analgesia. Smaller infants who were sedated after surgery were not given a morphine infusion in the recovery area but prescribed "as required" doses of morphine 25–50 μg kg^{-1} on the ward.

An infusion of 0.125 % bupivacaine was given for postoperative analgesia to patients in the extradural group, at an initial rate of 0.2 ml kg^{-1} h^{-1}, increased to a maximum of 0.3 ml kg^{-1} h^{-1} if analgesia appeared inadequate. Additional doses of 0.125 % or 0.25 % bupivacaine were given by anaesthesia personnel in the recovery area or on the ward at the request of the recovery or ward nursing staff. No formal attempt was made to evaluate the dermatomal levels of the extradural block during the study because of the unreliability of such measurement in this age group. The total dose of bupivacaine given to any child was limited to less than 1.6 mg kg^{-1} in any 4-h period (0.4 mg kg^{-1} h^{-1}) to avoid the risks of systemic accumulation and toxicity.

A 2.5-ml venous blood sample was taken after induction of anaesthesia, but before tracheal intubation for measurement of baseline adrenaline, noradrenaline, glucose, ACTH and cortisol concentrations. Subsequent samples were obtained 45 min after the start of surgery, at the end of surgery, 1 h and 24 h after surgery. All samples were placed immediately on ice. Samples for catecholamine assay (1.5 ml) were collected into heparinized tubes on ice, centrifuged at 4 °C and the plasma stored at −70 °C until assay by high pressure liquid chromatography (HPLC) and electrochemical detection after prior extraction with alumina [9]. Coefficients of variation for the adrenaline and noradrenaline assays were 6–11 % at 0.5 ng ml^{-1} and 3–5 % at 1 ng ml^{-1}, respectively. The limits of detection were 45 pg ml^{-1} for adrenaline and 30 pg ml^{-1} for noradrenaline. Whole blood glucose was measured by enzymatic technique (glucose oxidase). ACTH samples (200-μl) were kept in EDTA tubes and centrifuged at 4 °C within 1 h of collection. The plasma was stored at −70 °C and measured for ACTH concentration using a highly specific radioimmunoassay (Allegra HS-ACTH, Nichols Institute Diagnostics). Quality controls for the technique had coefficients of variation of 9.4 % at 3.5–6.4 nmol $litre^{-1}$, 6.4 % at 17–22 nmol $litre^{-1}$ and 3.9 % at 90–133 nmol $litre^{-1}$ and the lower limit of sensitivity of the assay was 3.3 nmol $litre^{-1}$. Cortisol samples (0.5 ml) were measured from serum by radioimmunoassay (Diagnostic Products Corporation's Double Antibody Kit). The assay is highly specific with a coefficient of variation of 5.9 % at 180 nmol $litre^{-1}$ and 7.9 % at 1260 nmol $litre^{-1}$. The lower limit of sensitivity is 9 nmol $litre^{-1}$. In addition, plasma bupivacaine was measured in samples from patients in the extradural group. The technique used an HPLC method [10] with a coefficient of variation for extraction of less than 5 % and a coefficient of variation for measurement of 2.86 % at 1 μg ml^{-1} and 2.12 % at 2 μg ml^{-1}.

Changes in the plasma concentrations of adrenaline, noradrenaline, ACTH and cortisol were evaluated via log transformation. The log transformation was used to reduce the skewness of the data in order to meet the assumptions of the statistical method used. Repeated measures analyses were used to model and test differences in each of the log responses. Time, treatment and their interaction were considered potential explanatory factors in the variation of the mean log responses. Preliminary evaluation of the correlation structures of each of the log responses suggested that the assumptions of equal variances and equal correlations were satisfied

[11]. Therefore, the *F* tests for a standard split-plot analysis were used to test for significant time and treatment effects. For this analysis, only times coinciding with treatment, namely 45 min, end of surgery and recovery, were included. Then, to determine if the log responses at 24 h returned to baseline values, paired *t* tests were performed on pretreatment and post-treatment values. In this study, the different hormonal and metabolic responses are correlated because they are measured on the same subjects and some adjustment for multiple comparisons might be indicated. However, the statistical resolution between groups is sufficiently large that the results are not affected by a variety of adjustments. The *P* values are reported in the unadjusted state. The paired *t* tests on pretreatment and post-treatment values are also not adjusted for multiple comparisons; here, because we were trying to "prove" the null hypothesis.

RESULTS

Patients in the opioid and extradural groups were similar in age, weight and type of surgical procedures (table I). The average duration of surgery was 99.7 (SD 50.4) min in the opioid group and 111.0 (47.9) min in the extradural group.

Intraoperative arterial pressure and heart rate remained within 20% of baseline values in both groups. The average systolic arterial pressure was 99.3 (12.8) mm Hg in the opioid group and 94.6 (15.6) mm Hg in the extradural group. The averaged heart rates were 131.0 (20.1) beat min^{-1} in the opioid group and 123.5 (19.4) beat min^{-1} in the extradural group. The average dose of fentanyl given during operation was 1.34 (0.6) $\mu\text{g kg}^{-1}\text{ h}^{-1}$. Fourteen of the 20 patients in the opioid group were judged as pain-free in the recovery room and the remaining six settled rapidly after a loading dose of morphine. A mean dose of bupivacaine 20.2 (9.2) $\mu\text{g kg}^{-1}\text{ h}^{-1}$ was given during surgery to control haemodynamic changes. Two patients in the extradural group were judged to be in pain in recovery and both settled after a 0.5-ml kg^{-1} injection of 0.25% bupivacaine (1.25 mg kg^{-1}). Restlessness and agitation were reported in six extradural patients on the ward, but these were treated satisfactorily with incremental doses of extradural bupivacaine. Four patients in each group were given supplementary paracetamol for pyrexia or pain.

Plasma adrenaline concentrations (fig. 1) increased significantly from baseline values by 45 min after the start of surgery in both groups (paired *t* tests, $P < 0.001$). In the opioid group, the adrenaline concentrations had returned to baseline values by 24 h (paired *t* test, $P = 0.65$), while in the extradural group they remained slightly increased at 24 h (paired *t* test, $P = 0.03$). Patients in the extradural group had significantly smaller concentrations of adrenaline than the opioid group (*F* test, $P = 0.005$).

Plasma noradrenaline concentrations (fig. 2) did not change significantly during or after surgery in the opioid group but, in the extradural group, concentrations decreased during surgery and were significantly less than those in the opioid group (*F* test, $P = 0.03$). The noradrenaline concentrations at baseline and 24 h were not significantly different for the opioid or extradural group (paired *t* tests, $P = 0.22$ and $P = 0.67$, respectively).

Baseline concentrations of blood glucose were within normal limits: the smallest values were 2.5 mmol litre^{-1} in the opioid group and 2.4 mmol

TABLE I. *Patient data (mean (range or SD)) and details of surgery*

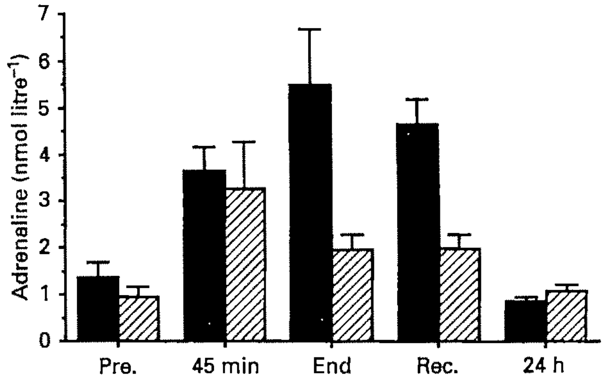

FIG. 1. Comparison of plasma adrenaline concentrations from patients receiving systemic opioid analgesia (■) or extradural bupivacaine analgesia (▨) before surgery (Pre.), 45 min after the start of surgery, at the end of surgery (End), 1 h after surgery (Rec.) and 24 h after surgery (means, SE). Adrenaline concentrations were significantly different in the two treatment groups (*F* test, $P = 0.005$).

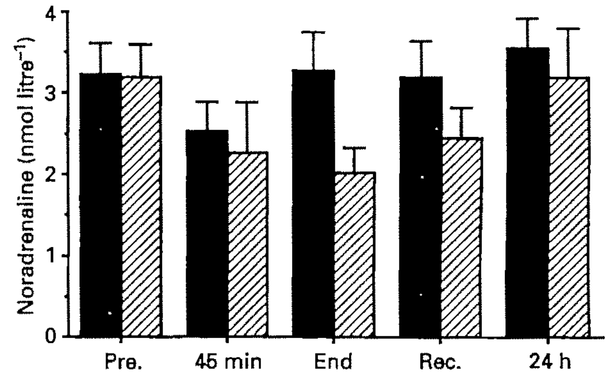

FIG. 2. Comparison of plasma noradrenaline concentrations from patients receiving systemic opioid analgesia (■) or extradural bupivacaine analgesia (▨) before surgery (Pre.), 45 min after the start of surgery, at the end of surgery (End), 1 h after surgery (Rec.) and 24 h after surgery (means, SE). Noradrenaline concentrations were significantly different in the two treatment groups (*F* test, $P = 0.03$).

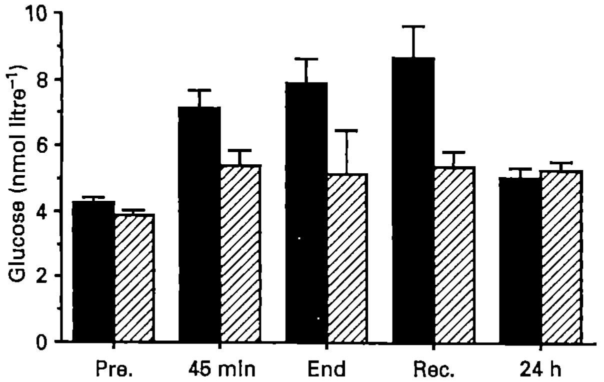

FIG. 3. Comparison of blood glucose concentrations from patients receiving systemic opioid analgesia (■) or extradural bupivacaine analgesia (▨) before surgery (Pre.), 45 min after the start of surgery, at the end of surgery (End), 1 h after surgery (Rec.) and 24 h after surgery (means, SE). Glucose concentrations were significantly different in the two treatment groups (*F* test, $P = 0.004$).

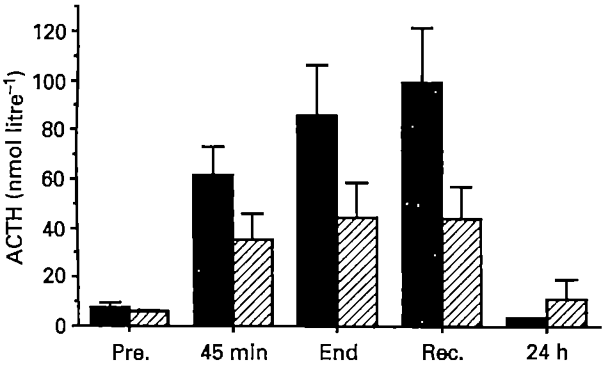

FIG. 4. Comparison of plasma ACTH concentrations from patients receiving systemic opioid analgesia (■) or extradural bupivacaine analgesia (▨) before surgery (Pre.), 45 min after the start of surgery, at the end of surgery (End), 1 h after surgery (Rec.) and 24 h after surgery (means, SE). ACTH concentrations were significantly different in the two treatment groups (*F* test, $P = 0.008$).

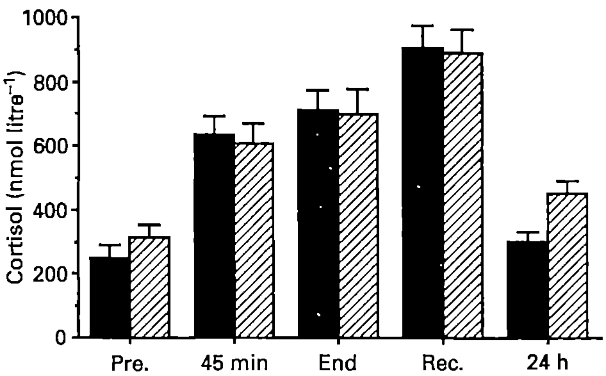

FIG. 5. Comparison of plasma cortisol concentrations from patients receiving systemic opioid analgesia (■) or extradural bupivacaine analgesia (▨) before surgery (Pre.), 45 min after the start of surgery, at the end of surgery (End), 1 h after surgery (Rec.) and 24 h after surgery (means, SE). There was no significant difference between the two treatment groups (*F* test, $P = 0.56$).

litre^{-1} in the extradural group. Whole blood glucose concentrations increased in both treatment groups during surgery (fig. 3), but were significantly greater in the opioid group (*F* test, $P = 0.004$). Blood glucose

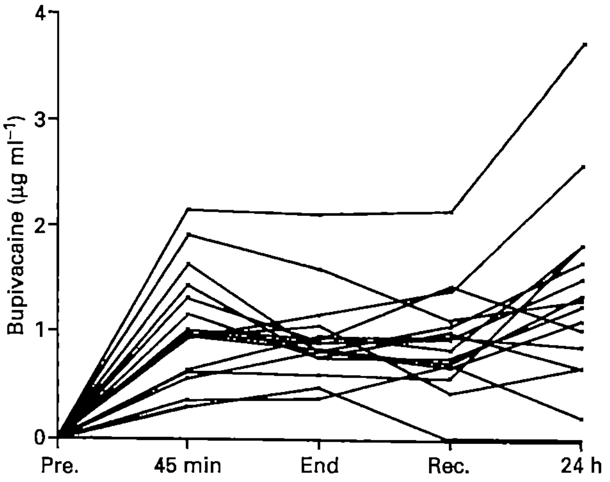

FIG. 6. Patient-by-patient display of plasma bupivacaine concentrations at 45 min after the start of surgery, at the end of surgery (End), 1 h after surgery (Rec.) and at 24 h after surgery.

concentrations remained greater than baseline in both groups at 24 h (opioid group: $P = 0.02$; extradural group: $P = 0.001$). Four patients in the morphine group and three in the extradural group required blood transfusion during the 24-h study period, and this may have contributed to the increase in blood glucose in those children.

ACTH concentrations (fig. 4) increased in both groups during surgery (paired *t* tests, $P < 0.001$), but the response was significantly greater in the opioid group (*F* test, $P = 0.008$). The 24-h concentrations were significantly different from baseline in the opioid group (paired *t* test, $P = 0.01$), but similar to baseline in the extradural group (paired *t* test, $P = 0.47$).

Plasma cortisol concentrations (fig. 5) increased significantly with surgery in both groups (paired *t* tests, $P < 0.001$), but the group-related differences in ACTH concentrations were not reflected in the associated plasma cortisol results (*F* test, $P = 0.56$). Power analysis indicated that the power of the test to detect a difference in the means of log cortisol of 0.1 between the two treatment groups was approximately 90%. Cortisol concentrations remained greater than baseline at 24 h after surgery in the extradural group (paired *t* test, $P = 0.004$), but not in the opioid group (paired *t* test, $P = 0.25$).

Individual plasma concentrations of bupivacaine are shown in figure 6. Postoperative infusions were not associated with increasing bupivacaine concentrations when analysed as a group, but there was large individual variation. Two patients had bupivacaine concentrations that increased to more than 2 µg ml^{-1} during the postoperative infusion, but no unusual behaviour was reported in those patients by the nursing staff. The patient attaining a 24-h value of 3.7 µg ml^{-1} was an 8.3-kg child who received a total of 25 mg of bupivacaine (3 mg kg^{-1}) during a 2-h procedure. The postoperative infusion delivered 0.3 ml kg^{-1} h^{-1} of 0.125% bupivacaine (0.375 mg kg^{-1} h^{-1}) and a single bolus of 2.5 mg was given at 16 h. These doses were just greater than designated guidelines for the study. The second patient weighed 10 kg and received bupivacaine 20 mg (2 mg kg^{-1})

during the 85-min procedure and had an infusion of 0.25 ml kg^{-1} h^{-1} (0.3 mg kg^{-1} h^{-1}) after surgery without further incremental bupivacaine. This patient was given a bupivacaine dosage well inside the guidelines for this study.

All patients entered into the trial completed the operative and recovery phases. Two patients in the bupivacaine group had to be changed to i.v. morphine analgesia in the postoperative period. The first patient, reported previously in detail [12], developed signs of an ascending block while receiving the postoperative infusion. Subarachnoid block, hypoglycaemia and bupivacaine toxicity were excluded from the diagnosis and the child had an uneventful recovery after the infusion had been discontinued. The second patient had to be transferred to a morphine infusion after the extradural cannula fell out 16 h after operation. Both these patients remained in the study, but their 24-h samples were excluded from analysis. In the morphine group, one patient was changed to pethidine analgesia because of urticaria and facial swelling and another required a second laparotomy at 26 h for bleeding after a Ladd's procedure. The 24-h blood samples from these patients were also excluded from the study.

DISCUSSION

General anaesthesia supplemented with either opioids or extradural local anaesthesia provides comparable postoperative analgesia [13]. However, in this study we have shown that extradural analgesia with 0.25% bupivacaine suppressed the operative increase in adrenaline, glucose and ACTH more effectively than fentanyl 1.3 μg kg^{-1} h^{-1}. Noradrenaline output was reduced by extradural analgesia, but the cortisol changes in the two groups were similar despite the different ACTH responses. We have used anaesthetic techniques that are compatible with routine clinical practice: opioid dosing that allowed immediate postoperative tracheal extubation with adequate postoperative analgesia, and intraoperative extradural dosing based on simple changes in heart rate and arterial pressure, rather than attaining a specific level of block before surgery.

While there are considerable adult data on the effects of anaesthesia on stress responses to surgery, data in infants are limited. Recent neonatal studies [1–3] for cardiac and non-cardiac surgery are not easy to compare with the present study: many of the neonates had abnormal baseline measurements because of preoperative stress or therapy [3] and data were presented subsequently as changes in variables rather than absolute values. We specifically chose elective procedures, and efforts were made to eliminate preoperative stresses at induction of anaesthesia by using premedication, gaseous induction and avoidance of parental separation when appropriate. The resulting preoperative values were within normal limits and allowed a subsequent analysis using absolute values. The study could have been further improved by limiting the investigation to a single intra-abdominal procedure. This was not done for practical reasons of patient availability, but the two groups were matched for operation type and duration of surgery. Nursing staff evaluating pain were aware of the group assignment and pain observations were used to guide analgesia management, not to compare the quality of analgesia formally. Blinding the observers to the type of analgesia used is possible [13], but confers additional complexity and we did not deem it necessary in this study.

Extradural anaesthesia may eliminate the increase in catecholamine concentrations in response to pelvic surgery in adults [4] and caudal bupivacaine has a similar effect [8] in children undergoing minor urogenital surgery. The effects of extradural analgesia on intra-abdominal surgery are less clear [14], but studies which have documented high levels of sensory block before abdominal incision are associated with some reduction in the adrenaline response and substantial reductions or even abolition of the noradrenaline response [15, 16]. The catecholamine responses after extradural analgesia in the present study are in keeping with this adult data. Extradural analgesia *per se* from T4 to T10 has no effects on adrenaline concentrations, but results in a decrease in noradrenaline concentration because of reduction in sympathetic outflow [17]. Although we were unable to document levels of conduction block before surgical incision, the reduction in noradrenaline response during surgery suggests that our infants had conduction blocks high enough to block splanchnic innervation.

Peak adrenaline concentrations in the opioid group were greater than those in adult studies [4, 15, 16], but similar to those in neonates undergoing cardiac surgery with a morphine–halothane technique [3]. Adrenaline concentrations had diminished by 1 h after surgery and were close to baseline values within 24 h. This is in contrast with adults in whom catecholamine concentrations continue to increase after surgery [4, 15, 16] and supports the view that stress responses in infants are greater in magnitude but of shorter duration than those in adults [18].

Changes in concentrations of catabolic hormones, such as adrenaline and cortisol, during surgery result in glycogenolysis and hyperglycaemia. The glucose responses in the present study are similar to adult data in abdominal and thoracic surgery [19], which have shown that extradural analgesia has a significant blocking effect. Neonatal studies of non-cardiac [1, 2] and prebypass cardiac surgery [3] have reported much larger increases in blood glucose concentrations, even in those patients who received large doses of sufentanil. However, baseline blood glucose concentrations were increased before operation and it is difficult to compare directly absolute values of glucose with previous studies because of the influence of perioperative glucose infusions on subsequent measurements [20]. We chose to avoid glucose infusions during surgery to eliminate this effect, but the postoperative use of glucose-containing solutions has affected our 24-h samples.

The greater ACTH concentrations in the opioid group did not induce an increased cortisol response. In adults, extradural analgesia can reduce ACTH and cortisol responses to lower abdominal surgery, but has little or no effect on the cortisol response to upper abdominal surgery [19]. In children also, extradural analgesia can suppress the cortisol response to minor lower limb and penile surgery [7], but there has not previously been any data on responses to abdominal surgery. Upper abdominal or thoracic surgery is a more potent stimulus to the stress response than more minor surgery and it has been claimed that this stimulus is sufficient to produce a maximal or near maximal response from the adrenal cortex [21, 22]. This view is supported by the observation that ACTH response to surgery is often in excess of that required to produce maximal cortical response [22], and that administration of exogenous ACTH during surgery is unable to elicit further increases in cortisol [23]. In the present study, the peak cortisol values of 906.8 (313.5) nmol litre^{-1} in the opioid group and 891.1 (332.0) nmol litre^{-1} in the extradural group are similar to the greatest values recorded in adult patients having abdominal or cardiac surgery regardless of anaesthetic technique [5, 24, 25]. Therefore, the smaller concentrations of ACTH in the extradural group may still have been sufficient to produce a maximal cortisol response. Certainly, the concentrations of cortisol are greater than those seen in previous paediatric studies [1, 2, 7, 26] and are equivalent to the greatest values observed in a group of neonates (non-survivors) undergoing cardiac surgery [27]. Other possible explanations for these observations should be considered. Extradural analgesia may influence the blood supply to the adrenal cortex or an alternative humoral mechanism may independently stimulate cortisol production. Several of the cytokines can stimulate the adrenocortical axis and these are produced at high levels during abdominal surgery [28].

Recent case reports of convulsions from systemic bupivacaine absorption have highlighted the potentially hazardous nature of continuous bupivacaine infusions in small children [29, 30]. All the five reported cases received large doses of bupivacaine in excess of 1.25 mg kg^{-1} h^{-1} and had concentrations greater than 5 μg ml^{-1}. Recommendations to limit dose rates to 0.4–0.5 mg kg^{-1} in infants and children and to 0.2–0.25 mg kg^{-1} in neonates [31] are reasonable, but do not necessarily prevent systemic accumulation. In the present study we limited the intraoperative dose to 2.5 mg kg^{-1} (0.25% bupivacaine 1 ml kg^{-1}) and the postoperative dose to 0.4 mg kg^{-1} h^{-1} (0.125% bupivacaine 0.3 ml kg^{-1} h^{-1} with bolus doses of 0.125% or 0.25% bupivacaine). These doses are well inside the recently recommended guidelines [31], and the majority of the patients had small concentrations of bupivacaine throughout the study. However, while there was no significant postoperative increase in bupivacaine concentrations for the group as a whole, there was considerable variability. Two of the patients did accumulate relatively large concentrations from the bupivacaine infusion (fig. 6), and it is likely that the concentrations would have continued to increase after 24 h [30]. It is essential, therefore, to remain alert for the signs of bupivacaine toxicity even when "safe" guidelines are used.

ACKNOWLEDGEMENTS

This study was supported by funding from the Department of Anaesthesia at The Royal Children's Hospital, Melbourne, Australia. We thank Dr Kester Brown for his support and suggestions.

VOLUME REPLACEMENT WITH HYDROXYETHYL STARCH SOLUTION IN CHILDREN

J. BOLDT, C. KNOTHE, E. SCHINDLER, H. HAMMERMANN, F. DAPPER AND G. HEMPELMANN

SUMMARY

In 30 consecutive children undergoing cardiac surgery, two different types of fluid were given randomly for volume replacement in the pre-bypass period. In group 1 (n = 15), low molecular weight hydroxyethyl starch solution (LMW-HES) (6% HES; mean molecular weight 200000 Da, molar substitution 0.5) and in group 2 (n = 15) 20% albumin (HA) was infused from the induction of anaesthesia until the start of cardiopulmonary bypass (CPB). In addition to haemodynamic values, various laboratory variables were measured before and after CPB until the morning of the 1st day after operation. The patients did not differ in diagnosis and conduct of CPB (lowest rectal temperatures: group 1 29.0 (SD 1.1)°C; group 2 29.4 (1.0)°C). Haemodynamic data (MAP, HR, CVP), anti-thrombin-III, fibrinogen, platelet count and coagulation variables were comparable between the groups until the 1st day after operation. Postoperative blood loss and the use of homologous blood or blood products were similar in all children. Albumin concentration increased after infusion of albumin (35–47 g litre^{-1}) and was significantly greater until the end of the operation compared with the LMW-HES-treated children. Colloid osmotic pressure, however, was similar in the two groups and returned to baseline values on the 1st day after operation (LMW-HES group 19.31 (1.2) mm Hg; HA group 18.0 (1.3) mm Hg). Post-bypass urine output and creatinine values also did not differ between the groups. Anaphylactic reactions were not observed in any of the patients. It can be concluded that LMW-HES solution can be used effectively and safely for volume replacement in the pre-bypass period in small children undergoing cardiac surgery. (Br. J. Anaesth. 1993; **70**: 661–665)

KEY WORDS

Anaesthesia: paediatric. Fluid balance: albumin, hydroxyethyl starch.

A proportion of children undergoing cardiac surgery need volume expansion in the pre-bypass period because of the vasodilator effects of the anaesthetics or surgical blood loss. A variety of fluids is recommended to enhance blood volume and improve haemodynamics in this situation, including homologous blood and blood products, crystalloids and albumin [1–3]. Albumin appears to be the fluid used most frequently for volume therapy in paediatric cardiac surgery. In contrast, in adults, synthetic colloids such as hydroxyethyl starch solution (HES) are used to treat volume deficits in various situations, including cardiac surgery procedures [4]. In several centres, HES has replaced albumin as the first choice for volume replacement. However, experience with HES for volume therapy in children is limited. The aim of this study was to establish if HES could be used safely for volume replacement in children undergoing cardiac surgery.

PATIENTS AND METHODS

We studied 30 consecutive children aged less than 3 yr and undergoing cardiac surgery, after approval by the institutional review board and with informed parental consent. Children undergoing reoperation or with pre-existing coagulation or renal abnormalities, or a haemoglobin (Hb) concentration less than 10 g dl^{-1} were excluded. Hypovolaemia was defined as a reduced central venous pressure (CVP) (< 6 mm Hg), ventilation-associated variations in arterial pressure, increase in heart rate or a decrease in arterial pressure (mean arterial pressure (MAP) < 50 mm Hg). Volume replacement was given after induction of anaesthesia until the start of cardiopulmonary bypass (CPB). According to a randomized sequence, either low molecular weight hydroxyethyl starch solution (LMW-HES) (6% HES; mean molecular weight 200000 Da; molar substitution 0.5) (LMW-HES Fresenius; Bad Homberg, F.R.G.) (*n* = 15) or 20% human albumin (HA) (HA, Behring, Marburg, F.R.G.) (*n* = 15) was given to achieve a stable haemodynamic state. All volume infusion was requested by anaesthetists who were not involved in the study and who were blinded to the volume given.

Anaesthesia and cardiopulmonary bypass (CPB)

Induction and maintenance of anaesthesia were comparable in both groups and consisted of weight-related doses of fentanyl, midazolam and pancuronium. Controlled mechanical ventilation ($F\text{I}_{O_2}$, ventilation frequency and volume) was adjusted according to pulse oximetry (Sp_{O_2}), end-expiratory carbon dioxide concentration and blood-gas analyses.

Five minutes before CPB, heparin 300 u. kg^{-1} was given to achieve anticoagulation. CPB was performed with membrane oxygenators (COBE VPCMLplus, Cobe Lab., Lakewood, Colorado, U.S.A.) and non-pulsatile perfusion (flow 2.4 litre min^{-1} m^{2}). Lowest rectal temperatures were similar between groups (LMW-HES 29.0 (1.1)°C; HA 29.4 (1.0)°C). Hypothermic cardiocirculatory arrest was not used. The extracorporeal circuit was primed with crystalloids 600 ml and 5% human albumin 250 ml. When necessary to maintain the pump volume, Ringer's solution was added. Packed red cells (RBC) were given when Hb was < 7 g dl^{-1}. Bretschneider's cardioplegic solution was used for myocardial preservation. After successful weaning from CPB, protamine was given in a 1:1 ratio with respect to the initial amount of heparin. Blood remaining in the extracorporeal oxygenation equipment was concentrated by a cell saver (Cell Saver III, Haemonetics, Munich, F.R.G.) and the autologous blood was retransfused until the end of the operation. The same surgical team operated on all patients.

Measured variables

Besides haemodynamic monitoring (heart rate (HR), mean arterial pressure (MAP), central venous pressure (CVP)), various laboratory values were measured from arterial blood samples: blood-gas analyses, colloid osmotic pressure (COP) (cut-off point of the membrane 20000 Da), electrolytes, fibrinogen, anti-thrombin-III, albumin, platelet count, overall coagulation tests. Measurements were made before volume infusion (baseline values), immediately before the start of CPB, during and after CPB, at the end of the operation, 5 h after the operation and on the morning of the 1st day after operation.

After operation, RBC were given when Hb was < 10 g dl^{-1}, fresh frozen plasma was given when bleeding exceeded 5 ml kg^{-1} h^{-1} and platelet count was > 50000 ml^{-1} (activated clotting time (ACT) < 200 s), platelet concentrates were administered when bleeding exceeded 5 ml kg^{-1} h^{-1} and platelet count was < 50000 ml^{-1} (ACT < 200 s). All volume therapy within the study period was given by paediatric intensive care specialists who were blinded to the grouping.

Statistics

Power analysis had been done before the study was started, to determine the number of patients which would be necessary to prevent a type II error in the statistical interpretation. All data are expressed as mean (SD). One- and two-factorial analyses of variance (including multivariate analysis of variance followed by Scheffé's test) were used for statistical interpretation. Chi-square test was used to analyse

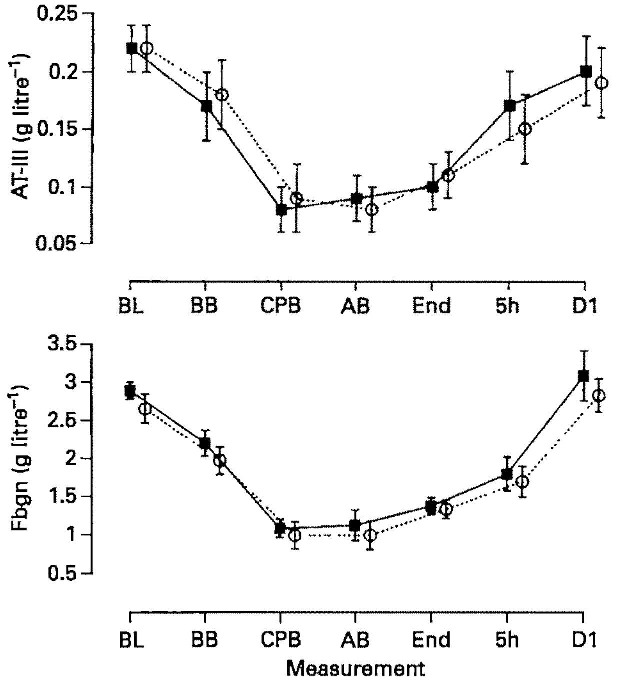

FIG. 1. Mean (SD) changes in anti-thrombin-III (AT-III) and fibrinogen (Fbgn) concentrations in the hydroxyethyl starch (○) and human albumin (■) groups (normal ranges: AT-III 0.15–0.30 g litre^{-1}; fibrinogen 2.0–3.5 g litre^{-1}). BL = Baseline; BB = before CPB; CPB = during CPB; AB = after CPB; End = end of operation; 5h = 5 h after operation; D1 = 1st day after operation.

differences for homologous blood use. $P < 0.05$ was considered to be significant.

RESULTS

Patient data, conduct of CPB (table I) and type of operation (table II) were comparable in both groups. Total volumes of LMW-HES 106 (11) ml and albumin 67 (22) ml were given in the pre-bypass period ($P < 0.05$). Fluid balance during CPB was also without group differences (table I).

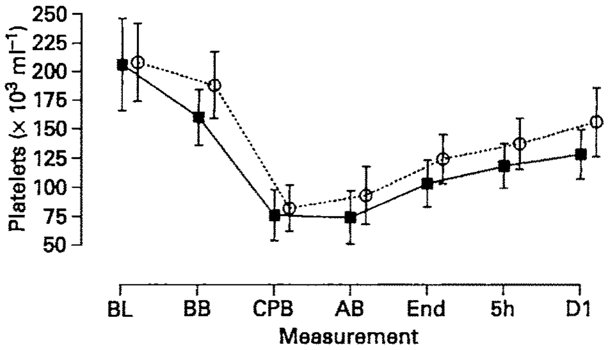

FIG. 2. Mean (SD) changes in platelet count in the hydroxyethyl starch (○) and human albumin (■) groups. Key to measurements as in figure 1.

Haemodynamic data (MAP, HR, CVP) in both groups showed a comparable course throughout (table III). Anti-thrombin III, fibrinogen and platelet count did not differ between the groups (fig. 1); neither did the general coagulation variables (thrombin time, partial thromboplastin time) and platelet count (fig. 2).

Plasma albumin concentration increased after infusion of 20% HA and was significantly greater until the end of the operation (fig. 3). COP, however, was similar between groups and recovered to baseline values on the 1st day after operation (fig. 3). Serum electrolytes and creatinine concentrations and postoperative blood loss were also comparable between groups (table III). In the HES group, urine output was significantly smaller during the bypass period, but was similar to that in the HA group in the remainder of the study (table III).

Postoperative blood loss until the 1st day after operation was comparable in the two groups (LMW-HES 27 (12) ml kg^{-1}; HA 25 (11) ml kg^{-1}) (table III). Total use of homologous blood, fresh frozen plasma and platelet concentrates was similar in both groups (table I).

None of the children had any signs of anaphylaxis during infusion of LMW-HES, or suffered sequelae attributable to the study.

TABLE III. *Mean* (SD) *changes in mean arterial pressure* (*MAP*), *heart rate* (*HR*) *and central venous pressure* (*CVP*), *and cumulative urine output and blood loss in the postbypass period until the 1st day after operation* (*1st day*) *in the two groups.* *$P < 0.05$

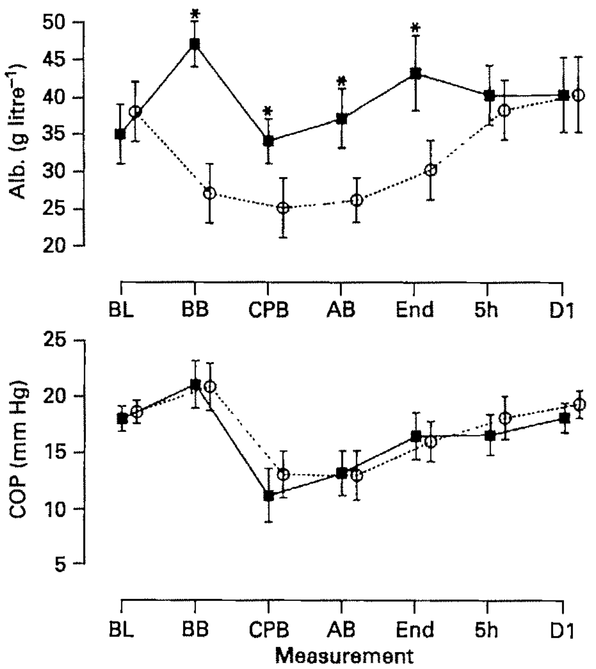

FIG. 3. Mean (SD) changes in albumin (Alb.) concentration and colloid osmotic pressure (COP) in the hydroxyethyl starch (○) and human albumin (■) groups (normal ranges: albumin 35–45 g litre^{-1}; COP 17–20 mm Hg). Key to measurements as in figure 1. *$P < 0.05$.

DISCUSSION

Replacement of fluid deficits is an essential aspect of cardiac surgery and is as important in the adult as in the infant or child. In the pre-bypass period, medication and blood loss may significantly alter the patient's blood or plasma volume [5]. One of the reasons for the use of albumin instead of crystalloids is the prevention of pulmonary oedema by augmenting colloid osmotic pressure. Thus maintenance of COP is postulated to be a desirable goal of volume replacement. Dilution of serum protein, particularly during CPB, decreases COP, which is associated with the risk of progressive expansion of the interstitial space. However, the effects of albumin depend on its movement between the intra- and extravascular compartments. This cannot be predicted because CPB may affect capillary permeability [6, 7]. Weaver and colleagues [8] have demonstrated that albumin molecules may extravasate into the interstitium and thus may favour fluid movement out of the capillaries because of their water binding capacity. In a study in critically ill adults comparing colloid infusions (5% albumin, Dextran and HES), there was a greater increase in extravascular lung water in the albumin group than in HES-treated patients [9]. In the present study, plasma concentrations of albumin were greater in the albumin-treated patients until the end of the operation than in the children receiving LMW-HES. COP, however, did not differ between groups. None of the children had signs of pulmonary oedema on the postoperative chest x-ray or progressive respiratory failure. Several studies of different plasma substitutes in adults have failed to show convincing differences between HES and albumin [10, 11]. The haemodynamic data obtained in the present study did not suggest any differences in the circulatory effects of the two solutions. Another objection to the use of HES solution for volume replacement in paediatric cardiac surgery may result from fear of alterations in coagulation. We used LMW-HES because it appears to have significantly less effect on haemostasis (and platelet function) than standard, high-molecular weight HES solution (6% HES 450000; molar substitution 0.7) [12, 13]. We did not observe any differences in coagulation factors between the two groups. Moreover, postoperative blood loss and use of blood or blood products were comparable in the two groups.

Changes in renal function may also be a reason for a limited use of synthetic colloids in this situation. In the present study, urine output and electrolytes were comparable in both groups, indicating comparable changes in renal function.

Possible accumulation of HES molecules in tissues, particularly in the reticulo-endothelial system, has often been an argument against the use of HES solutions in children. However, animal studies have not shown any changes in organ function as a result of storage of HES [14]. Moreover, LMW-HES appears less likely to cause tissue accumulation than other HES preparations [15]. Although "outcome" is not a good variable for assessing the importance of HES accumulation, none of our patients showed signs of organ dysfunction.

It is concluded that demonstration of the superiority of a particular fluid for volume replacement is difficult. However, LMW-HES has economic advantages in comparison with albumin solutions [16], and can be used safely in children undergoing cardiac surgery.

PHARMACOKINETICS AND PHARMACODYNAMICS OF KETAMINE ENANTIOMERS IN SURGICAL PATIENTS USING A STEREOSELECTIVE ANALYTICAL METHOD†

G. GEISSLINGER, W. HERING, P. THOMANN, R. KNOLL, H.-D. KAMP AND K. BRUNE

SUMMARY

In a randomized, double-blind study, we have examined the stereoselective disposition and pharmacodynamic characteristics of ketamine in surgical patients after i.v. administration of S(+)*-ketamine 1 mg/kg body weight (25 patients) or racemic ketamine 2 mg/kg body weight (25 patients).* S(+)*-Ketamine was not inverted to* R(−)*-ketamine. After racemate administration we observed statistically significant (*$P < 0.01$*) smaller clearance and volume of distribution for* R(−)*-ketamine compared with* S(+)*-ketamine. In contrast, the pharmacokinetic variables of* S(+)*-ketamine were not significantly different between treatment groups. Systolic and diastolic arterial pressure and heart rate increased significantly (*$P < 0.005$*) in both groups. At 1, 3 and 15 min after* S(+)*-ketamine administration, significantly greater increase in systolic and diastolic pressures were observed compared with the racemate group. There was no correlation between the changes in haemodynamic variables and plasma catecholamine concentrations, which remained unaffected after administration of the medications.* (Br. J. Anaesth. 1993; **70**: 666–671)

KEY WORDS

Anaesthetics, intravenous: ketamine,. Pharmacodynamics: enantiomers. Pharmacokinetics.

The relevance of stereochemistry to drug action and disposition is well documented [1–4]. Ketamine ((±)-2-(o-chlorophenyl)-2-(methylamino)cyclohexanone hydrochloride) is a dissociative anaesthetic agent which has been in clinical use as a racemate for more than 20 years [5–7]. Its use is associated with sensory and perceptual illusions, and vivid dreams after anaesthesia ("emergence reactions") [5], although diazepam alleviates these psychic sequelae [8].

Studies with the ketamine enantiomers have suggested both quantitative and qualitative differences in their effects on the central nervous system [9–13]. White and colleagues reported differences in their anaesthetic potency, intraoperative effects, postoperative analgesia and side effects in surgical patients [14]. It has been concluded that the S(+)-enantiomer has four times the potency of the R(−)-enantiomer and it may have significant clinical advantages in comparison with the racemic drug [14, 15]. Some studies of the pharmacokinetics of ketamine have used the sole enantiomers [14–16], but the pharmacokinetic parameters of a chiral compound should be assessed using stereoselective analytical methods [2]. Therefore the present investigation was designed to examine pharmacokinetic characteristics stereoselectively and to compare the pharmacodynamics of S(+)-ketamine with the currently available racemate (Ketalar) in surgical patients. Recommended equi-anaesthetic doses of racemic ketamine (2 mg/kg body weight) and S(+)-ketamine (1 mg/kg body weight) were administered i.v. in a random, double-blind fashion [14]. It was possible also to scrutinize the hypothesis that elimination of racemic ketamine is stereoselective, as has been speculated previously [4].

MATERIALS AND METHODS

Reference compounds

The enantiomers of ketamine and norketamine were supplied by Gödecke AG (Freiburg, Germany), and had chemical and optical purities of greater than 98.5%. The ampoules containing S(+)-ketamine (28.83 mg ml^{-1} as the hydrochloride, equivalent to S(+)-ketamine 25 mg ml^{-1}, lot CF 078099) and racemic ketamine (57.67 mg ml^{-1} as the hydrochloride, equivalent to ketamine racemate 50 mg ml^{-1}, lot CF 083109) were also supplied by Gödecke AG.

Patients

We studied 50 adult patients (10 females), ASA physical status I or II, undergoing minor surgery

lasting 1–2 h. The sample size was based on a power-based calculation of changes in systolic arterial pressure ($n = 22$ patients each group, 90 % power at a 5 % level on a two-sided t test). The usual exclusion criteria for ketamine anaesthesia were followed. The patients had no previous history or evidence of renal, hepatic, heart or pulmonary diseases, or of drug hypersensitivity. Smoking was not an exclusion criterion. Patients' characteristics are summarized in table I.

Study design

The study was approved by the University of Erlangen Medical Ethics Review Committee and written informed consent was obtained. Following enrolment in the study, patients were assigned in a random, double-blind fashion to one of two treatment groups by means of random permuted blocks of 10. One group ($n = 25$) received racemic ketamine, the second group ($n = 25$) S(+)-ketamine. In order to perform the study in a double-blind fashion, it was necessary to administer equal volumes of different concentrations of the two agents. The chemical composition of the enantiomer solution was identical to that of the commercially available product (Ketalar) except for the ketamine constituent.

Premedication comprised midazolam (Dormicum) 5 mg i.m. approximately 45 min before operation. A cannula was inserted into an antecubital vein in each arm and anaesthesia was induced with midazolam (Dormicum) 0.1 mg kg^{-1} i.v. over 30 s. Four minutes later, a single dose of ketamine 0.04 ml kg^{-1} was administered over 30 s, resulting in doses of S(+)-ketamine 1 mg kg^{-1} and racemic ketamine 2 mg kg^{-1}, respectively. Neuromuscular blocking drugs were used according to normal clinical practice. Four minutes after administration of ketamine the trachea was intubated. Ten minutes after ketamine administration, anaesthesia was maintained with nitrous oxide and 5 min later with nitrous oxide and enflurane. At the conclusion of the operation, enflurane and nitrous oxide were discontinued, residual neuromuscular block was antagonized and the trachea was extubated when clinically appropriate.

Haemodynamic effects

After arrival of the patient in the preoperative holding area and a rest of 10 min, the stable baseline systolic and diastolic arterial pressures and heart rate were measured using a Dinamap non-invasive monitor, followed by measurements at 2 min after midazolam was given and at 1, 3, 5, 7, 10 and 15 min after administration of ketamine.

Blood sampling and measurements of plasma catecholamines

Whole blood (4 ml) was obtained in cooled, heparinized tubes before administration of midazolam, 1 min before administration of ketamine and 3, 4, 5, 7, 10 and 15 min thereafter. The blood was cooled on ice for 10 min, and then centrifuged at 4 °C. Plasma (2 ml) was frozen and stored at −80 °C in tubes containing 40 µl of stabilizer (EGTA 9.5 g, glutathione 6.0 g, water 100 ml; Sigma Chemie, Deisenhofen, Germany) until analysis. Adrenaline and noradrenaline were measured using a slightly modified liquid chromatography assay with electrochemical detection as described previously [17]. The limit of quantification (the smallest concentration that could be determined during the inter-assay validation with either precision or accuracy of less than or equal to 15 %) was 20 pg ml^{-1} for both catecholamines. Quality control samples were included to verify the accuracy and precision of analysis. The samples were not stored longer than 3 weeks before analysis.

Collection of blood and analysis of ketamine enantiomers

Approximately 3 ml of heparinized blood was collected before and at 1, 3, 5, 7, 10, 15, 30 and 45 min and at 1.0, 1.5, 2.0, 3.0, 4.0, 6.0, 8.0, 10.0 and 12.0 h after administration of the ketamine bolus. The blood samples were centrifuged and the separated plasma stored at −30 °C with plasma quality control samples, pending analysis. The concentrations of ketamine and norketamine enantiomers were analysed by a high-pressure liquid chromatography method using a chiral alpha$_1$-acid glycoprotein column as described previously [18]. Separation was achieved without any derivatization procedure. One enantiomer of bisnortilidine (ethyl DL-trans-2-amino-1-phenyl-3-cyclohexane-1-carboxylate, as the hydrochloride) proved suitable as the internal standard. The detection wavelength was 215 nm for all substances. The retention times of the internal standard, S(+)-norketamine, S(+)-ketamine, R(−)-ketamine and R(−)-norketamine were about 14.5 min, 17.5 min, 25 min and 28 min, respectively. The separation factors for the chiral resolution of the enantiomers of ketamine and norketamine exceeded 1.15 and 1.75, respectively. The limit of quantification (the smallest concentration that could be measured during the inter-assay validation with either precision or accuracy of less than or equal to 15 %) was 40 ng/ml of plasma for ketamine and norketamine enantiomers. No reliance was placed on the detection limit (signal to noise ratio 3:1). Quality control samples were included to verify the accuracy and precision of stereoselective analysis.

Kinetic analysis of data

Non-compartmental pharmacokinetic variables [19] were calculated using the Topfit program package [20]. The terminal elimination rate constants (λ_z) were estimated by performing standard, unweighted linear least-squares regression analysis of the linear segment of the plasma log concentration–time data. The terminal elimination half-life ($T_{\frac{1}{2}}$) was calculated by dividing 0.693 by the absolute value of λ_z. The area under the drug concentration–time curve ($AUC_{0-\infty}$) was estimated by the linear and log-linear trapezoidal rule with extrapolation to infinity using the terminal elimination rate constant, λ_z. Total clearance (*Cl*) was calculated by dividing the administered dose by the AUC. Mean residence time (MRT) was calculated using the area under the first moment curve (AUMC), divided by the AUC. The volume of distribution at steady state (V^{ss}) was estimated by the product of *Cl* and MRT. *Cl* and V^{ss} for the ketamine enantiomers after administration of the racemate were calculated by considering the dose of the enantiomers to be equal to 50% of the administered dose of the racemate.

Statistical analysis of data

The mean and SD, and the 95% confidence limits were used to express the central tendency of the data. Categorical variables were evaluated by chi-square analysis.

Raw data were submitted to analysis of variance (MANOVA for repeated measures—univariate—with repeated measures as "within-subject-factor" and treatment as "between-subject-factor").

The pharmacokinetic variables were analysed using two-sided Student's *t* test for paired or unpaired data, as appropriate.

t Tests were used in order to establish differences between data (haemodynamic effects, catecholamines) before and after administration of the trial medications.

In order to compare the effects of S(+)-ketamine with those of racemic ketamine, differences between data obtained after and before administration were calculated and then submitted to *t* tests for comparison.

P values < 0.05 were considered to be statistically significant. The SPSS PC+ program version 4.0 and the PC-SAS program version 6.03 were used for statistical evaluation of the data.

RESULTS

Data from four patients in the S(+)-ketamine group and one patient in the racemate group could not be included in the pharmacokinetic calculation because of unexplained fluctuations in plasma concentrations of ketamine. Because of technical problems, data from only 34 patients could be used for reliable determination of plasma catecholamine concentrations. The groups were comparable in patient characteristics (table I). All analytical assays met the acceptance criteria established before the onset of study sample analysis [18, 21]. The mean predicted concentrations of plasma quality control samples were within 3 and 11% or 5 and 17% for ketamine enantiomers or catecholamines, respectively.

The mean plasma concentration–time profiles for ketamine and norketamine enantiomers after administration of S(+)-ketamine 1 mg kg^{-1} or racemic ketamine 2 mg kg^{-1} are shown in figures 1 and 2, respectively. S(+)-Ketamine was not inverted to its optical antipode as determined by plasma analysis (fig. 1). After administration of racemate, the plasma concentration profiles of the enantiomers of ketamine and norketamine were similar (fig. 2). Pharmacokinetic variables indicated a high clearance and a moderately large volume of distribution for the ketamine enantiomers (table II), similar to data published previously [15]. The calculated parameters of S(+)-ketamine were not statistically different between treatment groups (table II). Furthermore, the pharmacokinetic variables of S(+)-ketamine following administration of the single S(+)-enantiomer were also similar to those of R(−)-ketamine after administration of the racemate (table II). However, after administration of racemate a statistically significantly smaller clearance of 13.6% (16.5 (SD 4.8) ml min^{-1} kg^{-1} compared with 19.1 (7.2) ml min^{-1} kg^{-1}; $P < 0.01$) and smaller volume of distribution at steady state of 8.6% (3.01 (1.24) litre kg^{-1} compared with 3.29 (1.29) litre kg^{-1}; $P < 0.01$) for R(−)-ketamine compared with S(+)-ketamine were found (table II).

Haemodynamic variables (systolic and diastolic arterial pressures, heart rate) increased significantly in both groups after administration of ketamine (fig. 3). There was a statistically significant difference between groups in systolic pressure at 1 min ($P < 0.003$), 3 min ($P < 0.0001$) and 15 min ($P < 0.001$) after administration of ketamine, in diastolic pressure at 1 min ($P < 0.005$), 3 min ($P < 0.0001$) and 15 min ($P < 0.001$) after administration of ketamine and in heart rate at 1 min ($P < 0.05$), 3 min ($P < 0.05$) and 10 min ($P < 0.05$) after administration of ketamine. Plasma adrenaline and noradrenaline concentrations increased and decreased similarly in both treatment groups (table III) without reaching statistical significance over the period investigated. There were no correlations between changes in haemodynamic variables and plasma concentrations

of ketamine, norketamine enantiomers or catecholamines.

DISCUSSION

It has been shown that a single dose of S(+)-ketamine 1 mg kg^{-1} produced the same EEG slowing and depth of anaesthesia as 2 mg kg^{-1} of the racemic compound [14, 15]. However, it was not known if this was a reflection of pharmacodynamic differences or stereoselective disposition. We have now examined this question using a novel, validated stereoselective assay [18].

After administration of the pure S(+)-enantiomer, no R(−)-ketamine was detected, suggesting that no inversion occurred after S(+)-ketamine. After administration of the racemic compound, the plasma concentrations of R(−)- and S(+)-ketamine of each patient were similar; therefore, inversion from R(−)- to S(+)-ketamine seems unlikely. However, this observation is not conclusive, because a possible inversion from the R(−)- form to the S(+) form could be masked by, for example, different stereoselective clearances resulting also in similar concentration profiles of both enantiomers. In fact, after administration of the racemate, we found a statistically significant ($P < 0.01$) smaller clearance of R(−)-ketamine compared with S(+)-ketamine (16.5 ml min^{-1} kg^{-1} *vs* 19.1 ml min^{-1} kg^{-1}). This finding corresponds with *in vitro* data suggesting a significantly greater metabolism of S(+)-ketamine compared with its optical antipode, whereby R(−)-ketamine inhibited the metabolism of the S(+)-enantiomer [22, 23]. These *in vitro* data, however, would also suggest greater metabolism of S(+)-ketamine after administration of pure S(+)-ketamine compared with administration of the racemate. However, this finding is not consistent with our data (table II). Possibly small differences in rates of metabolism in the presence of large interpatient variability could be the explanation. Nevertheless, the differences in stereoselective disposition after administration of racemate may be clinically relevant. The inhibition of metabolism of S(+)-ketamine by the R(−)-enantiomer as found in *in vitro* experiments [22, 23] could account for the prolongation of recovery observed after administration of racemic ketamine as speculated by White and colleagues [15]. However, based on plasma clearance calculations, we could not find evidence that R(−)-ketamine inhibited the metabolism of S(+)-ketamine (table II). Further investigations could clarify the clinical relevance of the stereoselective metabolism also in connection with a stereoselective pharmacokinetic interaction of a benzodiazepine and ketamine, described previously using racemic ketamine and non-stereoselective methods [24].

The cardiovascular changes produced by ketamine are well documented [25, 26] also for the pure enantiomers [15]. It has been reported that the hypertensive effects of ketamine may be reduced by benzodiazepines (e.g. diazepam) given 5–10 min before administration of ketamine [27]. White and colleagues [15] administered S(+)-ketamine 25 mg min^{-1}, R(−)-ketamine 75 mg min^{-1} and racemic ketamine 50 mg min^{-1} over a 5–7 min interval by constant infusion (but without midazolam premedication) and found maximal increases in mean arterial pressure and heart rate of 42–59% and 56–85%, respectively. There was no significant difference in haemodynamic variables between the three groups. In our study, the maximal increases above baseline values in systolic pressure, diastolic pressure and heart rate were 27%, 29% and 28% in the S(+)-ketamine group and 26%, 27% and 20% in the racemate group, respectively. These data suggest that the S(+)-enantiomer contributed mainly to the cardiovascular stimulation. Haemodynamic variables increased constantly in the S(+)-ketamine group, whereas in the racemate group these variables increased only 5 min after administration of ketamine (fig. 3). This might be a result of different S(+)-ketamine plasma concentration profiles immediately after administration of ketamine. The mean S(+)-ketamine plasma concentration was 2635

(2566) ng ml^{-1} 1 min after administration of pure s(+)-enantiomer, but after the racemate, the mean s(+)-ketamine concentration was only 1817 (1884) ng ml^{-1}.

It has been suggested that cardiovascular stimulation by ketamine is caused by increased sympathetic nervous system activity, with enhanced catecholamine release secondary to depression of baroreceptor reflex activity [28]. However, our study has shown, that plasma concentrations of adrenaline and noradrenaline were unaffected by either s(+)-ketamine or the racemic compound. This observation is in accordance with other studies [29, 30]. Moreover, it has been shown that the increase in plasma concentrations of catecholamines after ketamine occurred only when premedication with benzodiazepines was avoided [27, 31]. Our results support the observations of White, Way and Trevor [6] that "ketamine produces its sympathomimetic actions primarily by direct stimulation of CNS structures".

We conclude that the disposition of ketamine enantiomers after administration of racemate is stereoselective, and suggest that the use of s(+)-ketamine is more rational than use of the racemic compound.

ACKNOWLEDGEMENTS

We thank Dr B. Raffelsberger (Parke Davis, Freiburg) for the generous supply of ketamine and norketamine enantiomers and Dr K.-O. Vollmer (Parke Davis) and Dr B. Gebhardt (Parke Davis) for helpful discussions.

REVIEW ARTICLE

PREVENTION AND TREATMENT OF HYPOTENSION DURING CENTRAL NEURAL BLOCK

A. F. McCRAE AND J. A. W. WILDSMITH

The management of hypotension occurring during central neural block is a subject of some contention, with proponents for the use of either volume loading or vasopressors expressing dogmatic views. It is important not to be too specific in the approach to this problem and to treat each patient on individual merit, recognizing that many factors may influence arterial pressure during anaesthesia and surgery.

CONTROL OF ARTERIAL PRESSURE

Arterial pressure is the product of cardiac output and systemic vascular resistance and both of these variables are influenced by many factors (fig. 1). Cardiac output is determined by venous return according to the Frank Starling law. Venous return is influenced by gravity, the calf muscle pump, intrathoracic pressure and the degree of venomotor tone, which is matched to circulating blood volume. Systemic vascular resistance is determined by sympathetic vasomotor tone and by the influence of hormones such as renin, angiotensin, aldosterone and antidiuretic hormone. Endogenous vasopressin (antidiuretic hormone) also contributes to maintenance of arterial pressure during extradural anaesthesia [51]. The vasomotor centre in the brain stem controls the degree of sympathetic tone in a feedback loop involving the baroreceptors. Other factors affecting arterial pressure such as pain, exercise and emotion act directly through the vasomotor centre, which also receives input from the chemoreceptors.

Changes within the microcirculation may also influence arterial pressure, although it is more usual to think of those factors as being responsible for autoregulation of flow. There are two main mechanisms: myogenic and chemical. Myogenic autoregulation acts via stretch receptors in vessel walls which cause them to constrict when pressure is decreased. Chemical autoregulation is mediated by the local concentration of vasoactive metabolites. In the presence of vasodilatation, as produced by sympathetic block, an increase in flow washes out the metabolites and produces reflex vasoconstriction.

ORGAN PERFUSION

Although it is arterial pressure that we measure and adjust, it is important to remember that organ flow is the vital factor. Compensatory mechanisms ensure that flow to vital organs is maintained over a wide range of pressures.

Coronary blood flow is autoregulated between 60 and 150 mm Hg. If coronary perfusion pressure decreases, the myocardium becomes relatively hypoxic and ADP accumulates. This is converted to adenosine, a potent coronary vasodilator, which restores local blood flow. A decrease in arterial pressure results in decreased left ventricular work and oxygen demand. Therefore hypotension may have a benign effect unless there is concomitant tachycardia or a significant pressure gradient across the aortic valve, both of which impair coronary artery filling during diastole.

Cerebral blood vessels are devoid of sympathetic nerve supply and autoregulation of flow occurs between 50 and 180 mm Hg by reflex arteriolar constriction in hypertension or vasodilatation in hypotension. Thus normal cerebral blood flow is maintained until mean arterial pressure is less than 50 mm Hg. At such a pressure, ischaemia occurs, leading to local hypercapnia and hypoxia, both of which stimulate the vasomotor centre chemically to increase sympathetic tone and systemic vascular resistance in an attempt to restore arterial pressure.

Renal autoregulation occurs between 80 and 180 mm Hg. The afferent glomerular arteriole has a myogenic response to stretch and constricts with hypertension and dilates with hypotension to maintain a constant renal perfusion pressure. This can be overriden by the sympathetic innervation of the kidney. A small decrease in arterial pressure produces sympathetic stimulation and causes vasoconstriction of the efferent arteriole to maintain filtration pressure in the glomerulus in the presence of decreased renal blood flow. A more marked decrease in arterial pressure and more intense sympathetic stimulation results in constriction of the afferent

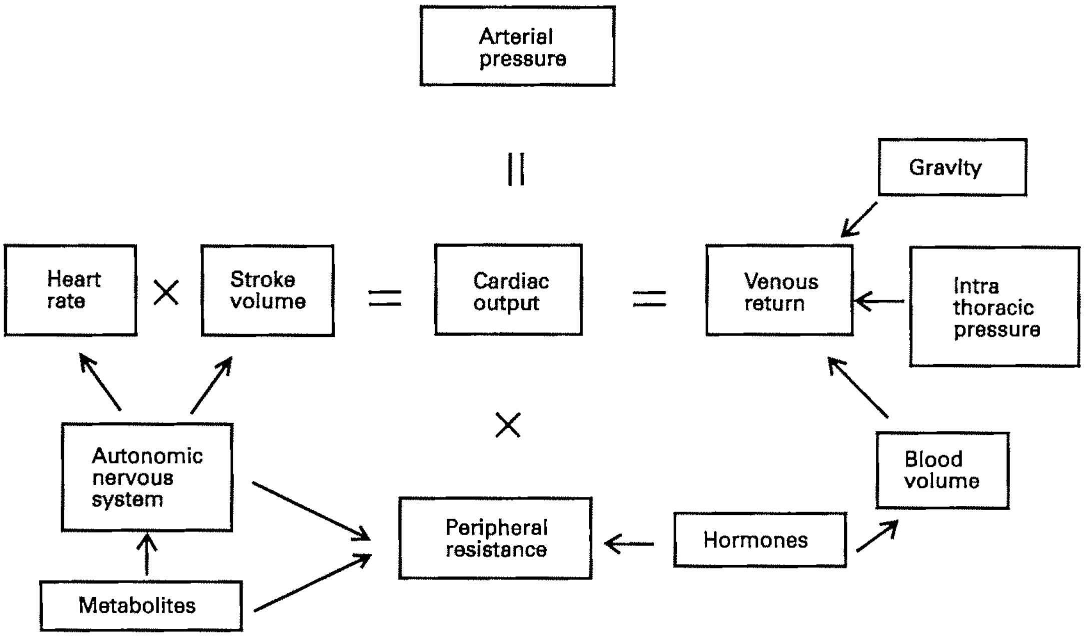

FIG. 1. Major factors influencing arterial pressure during central nerve block.

arteriole and a decrease in both renal blood flow and glomerular filtration. In clinical practice, glomerular filtration rate is reduced only to a small extent (10 %) during central neural block and this is not enough to cause significant impairment of normal renal function [30].

CIRCULATORY EFFECTS OF CENTRAL BLOCK

Hypotension during central neural block is mainly a result of decrease in systemic vascular resistance which occurs by block of preganglionic sympathetic fibres. This allows vasodilatation and an increase in venous capacitance with venous pooling, unless gravity is used to maintain venous return. Hypotension is more likely to occur in dehydrated or hypovolaemic patients.

The major factor in the development of hypotension is the level of block. The sympathetic outflow is between T1 and L2, so that a block below that level has no effect on arterial pressure, but one to T8 "sympathectomizes" the lower half of the body. The sympathetic supply to the adrenal medulla is from T8 to L1 and central neural block alters arterial pressure by inhibition of the systemic release of catecholamines. Fibres from T2 to T4 provide the sympathetic supply to the heart, and decreased contractility and bradycardia (from unopposed vagal activity) ensues if they are blocked. *Although vagal overactivity may cause severe hypotension in individual patients,* changes in arterial pressure relate more usually to the level of block than to vagal efferent activity as measured by ECG R–R intervals [13]. A block as high as T1 totally removes the ability of the body to compensate for other circulatory changes in addition to producing extensive vasodilatation.

The level of sympathetic block is in general higher than the sensory block, but the situation is complex. The differential cephalad extent of block has been reported as two segments if loss of temperature discrimination is used as the measurement of sympathetic block [23] and six segments if thermographic imagery techniques are used to measure small changes in skin temperature [6]. Sympathetic block may also be incomplete. Only 60 % of patients undergoing spinal anaesthesia had complete sympathetic block as demonstrated by skin conductance response measurements [41]. Such measurements correlate with changes in conductance resulting from sweating with sympathetic nervous system activity, although other workers have cast doubt on the use of this method as a measure of the completeness of sympathetic block [31]. The duration of sympathetic block may not be as long as previously thought, and one study has shown that motor and sensory block outlast it [3]. However, this may simply indicate that hormonal and capillary reflexes compensate for the sympathetic block and obscure its effects.

Type of central block

There are differences between spinal and extradural block. The degree of sympathetic block tends to be greater, and the onset of hypotension tends to be faster, after spinal than after extradural injection, because the speed of onset of the block is faster than the development of physiological compensation [14]. Individual variations in technique such as speed of injection, the use of barbotage in spinal or an incremental technique in extradural block [15] may cause different degrees of hypotension by altering the height of block obtained and the rate at which it develops.

Alterations to the local anaesthetic solutions, such as changing the baricity of the agent used in spinal anaesthesia to manipulate the height of block, may influence the development of hypotension [1]. Adding adrenaline tends to produce a more profound central block and therefore greater decreases in mean arterial pressure and systemic vascular resistance, but the changes may be modified further by the direct effect of adrenaline on peripheral resistance, heart rate and cardiac output. The use of alkalinized

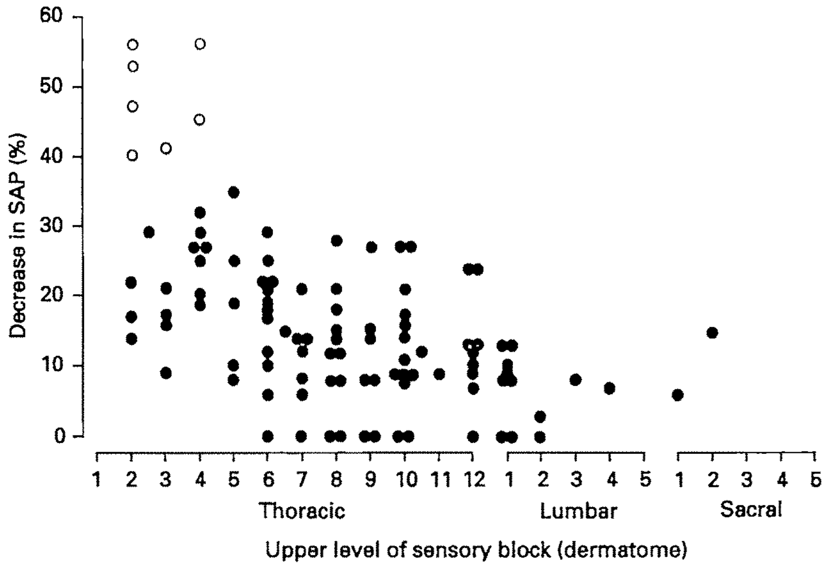

FIG. 2. Relationship between upper level of sensory block and per cent decrease in systolic arterial pressure (SAP) in 100 patients given amethocaine in a variety of solutions. No prophylactic treatment was given. O = Seven patients who required treatment with atropine or ephedrine because of clinical circulatory inadequacy. (Reproduced with permission [38].)

lignocaine in extradural block is associated with both a greater degree and more rapid onset of hypotension than non-alkalinized solutions [50]. Finally, the systemic effect of a large dose of local anaesthetic is myocardial depression and this may also influence the arterial pressure.

THE OBSTETRIC PATIENT

The obstetric patient presents additional problems. In the supine position, the inferior vena cava may be occluded completely by the pregnant uterus. Unless adequate venous return occurs through the collateral system of extradural and azygous veins, decreased arterial pressure and uterine blood flow result [35]. The aorta may also be compressed and, although this may not produce symptoms in the mother, uterine blood flow decreases, resulting in fetal distress and neonatal depression. This syndrome of supine hypotension by aortocaval compression may occur from 20 weeks onwards [8] and is relieved by the mother adopting the left lateral position. Although delivery of the baby also relieves the situation, it may be associated with an acute loss of circulating volume and compensation may be impaired seriously if the block is extensive.

TREATMENT

Defining hypotension

A variety of options is available for both prevention and treatment of hypotension caused by central block. These have been researched extensively, but there are many problems in comparing studies in this field. Although the variability of "resting" arterial pressure is widely recognized, it is unusual for the status of the control figure to be defined clearly. Second, arbitrary definitions of hypotension have been chosen by different authors: systolic arterial pressure < 100 mm Hg or < 90 mm Hg, 20 % or 30 % decreases from baseline or any 30-mm Hg decrease in systolic pressure have been used. In some studies, changes in mean rather than systolic arterial pressure were analysed and relatively few studies have been fully randomized. Frequently, only patients who became hypotensive were studied!

Such factors have favoured the preconceived notion that all patients become hypotensive during central nerve block and as a result there are few studies with true control groups in which no intervention was used. Figure 2 [38] relates the percent change in systolic pressure to the level of block in 100 non-obstetric patients who received a variety of regional techniques, but no prophylaxis for hypotension other than a 5° head-down tilt. The risk of hypotension increased with height of block, but many patients with extensive blocks had minimal changes in arterial pressure.

General points

Because a high level of block is a major determinant of the development of hypotension, choosing a block limited to suit the planned procedure prevents unnecessary decreases in arterial pressure. Haemorrhoidectomy does not require a block higher than S1, whereas abdominal hysterectomy needs a block of T10 at least. In any patient receiving a central nerve block, venous return should be maintained by a slight (5–10°) head-down tilt to eliminate venous pooling in the legs, and by the use of left-lateral tilt in obstetric patients.

Infusions and combined blocks have been advocated as being less likely to produce significant hypotension. When continuous extradural infusions are used in labour, the majority of episodes of hypotension occur in relation to the initial loading dose [20]. If a bolus of the dilute solution intended for the infusion is used as a loading dose rather than a more concentrated local anaesthetic, the incidence of hypotension is reduced from 35% to 7%, although there is some increase in onset time [40].

The combined spinal-through-extradural needle technique decreases the incidence of hypotension by producing rapid establishment of a spinal block of the lower segments followed by careful extension of the block using bolus extradural injections. During Caesarean section using the combined technique, the incidence of hypotension was 33% compared with 53% in a conventional extradural group. Another advantage was a reduction in the total dose of local anaesthetic to approximately 33% of that used in the conventional group [56].

The use of combined spinal-through-extradural needle techniques have *not* produced problems of accidental high block with associated severe hypotension [11, 18, 33]. However, spinal block performed *after* extradural anaesthesia may result in a very extensive block and severe hypotension [2, 64]. Possibly, local anaesthetic passes through the puncture wound in the dura or, more likely, the subarachnoid space is compressed by the large volume of local anaesthetic present in the extradural space [2].

Hypotension during spinal anaesthesia may be reduced using a catheter technique. A retrospective study of elderly patients undergoing orthopaedic surgery found that hypotension occurred less frequently, and fewer doses of vasopressor were required during continuous spinal anaesthesia than during continuous extradural block [65].

Mechanical methods

Several mechanical methods of compressing the lower limbs, in order to encourage venous return, have been used with varying degrees of success. In studies of Caesarean section under spinal anaesthesia, the application of Esmarch bandages from ankle to mid-thigh decreased the incidence of hypotension from 83% to 16% [4], and inflatable full length leg splints (normally used for fracture stabilization) from 83% to 48% [22], but inflatable boots produced no significant effect [27]. However, a different volume of fluid was given in each of these studies: 20 ml kg^{-1} in the first, 15 ml kg^{-1} in the second and 10 ml kg^{-1} in the third. During extradural Caesarean section, elastic bandages were found to reduce the incidence of hypotension from 83% to 13% [21], but graduated compression stockings made no significant difference, the incidence of hypotension being 30% in both groups [34]. However, the volumes of fluid administered were different; Ringer's lactate solution 15 ml kg^{-1} in the first study and only 500 ml in the second. It would appear that none of these methods is entirely reliable in preventing hypotension.

Additional mechanical methods have been used in obstetric patients to eliminate supine hypotension, by displacing the uterus, either by a special device or by adopting the full left-lateral position. In pregnant women at term, a comparison between the supine or left-lateral "wedged" positions with either the Colon–Morale or Kennedy uterine displacement device found that the wedge was more effective than mechanical displacement of the uterus [19]. One interesting study looked at the inter-relationship between fluid loading and mechanical displacement in patients undergoing Caesarean section with a spinal anaesthetic. In elective patients, the incidence of hypotension was 92% in an untreated control group, 57% after 1000 ml of crystalloid and 53% with mechanical displacement and crystalloid [10]; in a group of emergency Caesarean sections, the incidences were 50%, 46% and 15%. The lesser frequency of hypotension in the labouring groups was perhaps the result of contractions autotransfusing blood from the uterine vessels to the general circulation. It seems that mechanical devices have little to offer, as they merely displace the centre of gravity, whereas tilt alters the direction of force.

Volume loading

The effect of i.v. fluid loading is to increase stroke volume and cardiac output [58], although these return to control values after institution of a central block. Both crystalloid and colloid have been used to compensate for these changes and arguments have been advanced for the use of each. In general, the use of crystalloid requires a larger volume than colloid and this might be expected to cause pulmonary oedema in an at-risk patient, but one study found this not to be the case [68]. Colloid may stay in the intravascular compartment longer, but is more expensive and some of the solutions confer a small, but significant, risk of anaphylaxis [63].

Large volumes of fluid may not be desirable in some circumstances, and may be frankly dangerous in elderly patients with poor cardiac function, in whom there is a risk of pulmonary oedema and cardiac failure. Routine volume loading may be unnecessary in these patients unless they are dehydrated. Ringer's acetate solution 0, 8 or 16 ml kg^{-1} was given to elderly patients having lower limb or lower abdominal operations under spinal anaesthesia, but the incidence of hypotension (24–32%) was not significantly different between the groups [12]. Obstetric patients are also at increased risk of pulmonary oedema, because interstitial lung water is increased during the puerperium [39]. A possible further complication of large volume administration is the development of urinary retention. Sympathetic vascular tone returns before bladder sensation as a block regresses, so that overdistension occurs while the patient is unaware [7].

In a small study of spinal anaesthesia for Caesarean section or vaginal delivery, pretreatment with 1000 ml of 5% glucose in Ringer's lactate solution prevented any significant decrease in arterial pressure from baseline, whereas the control group all became hypotensive (to a greater extent in the patients with a higher block for Caesarean section) [71]. A larger preload (2000 ml) of Ringer's lactate solution was used in an open study of Caesarean section under extradural block and only 6.7% of patients had a decrease in arterial pressure greater than 20% from baseline [36]. Therefore volume loading was concluded to be a satisfactory method of preventing hypotension. In contrast, a recent study of Caesarean section under spinal anaesthesia compared volume loading with crystalloid 20 ml kg^{-1} given over 20 or 10 min. The incidence of hypotension was still 60 % and 70 %, respectively, and three of 10 patients in the latter group had unacceptable increases in central venous pressure [60].

It has been argued that colloid produces a more sustained and more effective expansion of the intravascular space and several studies have compared colloid with crystalloid in the prevention of hypotension during central neural block.

In extradural Caesarean section, a regimen of Ringer's lactate 500 ml + gelatin 500 ml solutions proved superior to 1000 ml of Ringer's lactate solution and reduced the incidence of hypotension from 45 % to 10 % [25]. Similarly, Dextran 70 solution 7.5 ml kg^{-1} was more effective than Ringer's lactate solution 15 ml kg^{-1}, reducing the incidence of hypotension from 25 % to 5 % [70]. Using thoracic electrical bioimpedance, the latter study also demonstrated a smaller thoracic fluid index, indicating less lung water in the patients given colloid. In patients having lower limb operations under extradural block, volume loading with 500 ml of low and medium molecular weight hetastarch, Dextran 70 and balanced salt solution were compared [32]. The requirement for etilefrine (ethyl-norphenylephrine) to maintain arterial pressure was not significantly different between the groups, although there was a trend towards greatest usage in the balanced salt solution group, less in the hetastarch groups and least in the Dextran group.

However, other studies of extradural Caesarean section have shown no benefit of colloid compared with crystalloid. One compared Ringer's lactate solution 1200 ml, with similar volumes of Ringer's lactate solution combined with albumin and found no significant difference in mean arterial pressure or ephedrine requirement [55]. Another study compared Ringer's lactate solution 2000 ml with Hetastarch solution 1000 ml and also found no difference between the groups [45]. During Caesarean section under spinal anaesthesia, Ringer's lactate solution 15 ml kg^{-1} with 5 % glucose was compared with the same solution containing 5 % albumin; 50 % of the patients in each group were then given ephedrine 25 mg by i.m. injection. No patient given albumin developed significant hypotension, whereas hypotension occurred in approximately 30 % of the crystalloid groups, with or without ephedrine [42].

Taken overall, these studies are contradictory, even in the incidence of hypotension in the "control" groups. Infusion of large volumes of fluid has been shown to overload the right side of the heart [46] and requires that all patients are "treated" before the spinal or extradural needle is sited. This may result in a significant proportion of patients who would not have become hypotensive receiving a large fluid load. Perhaps a more physiological approach to the treatment of hypotension induced by sympathetic block is to counteract it as it occurs, by using sympathomimetic drugs.

Vasopressors

A large proportion of the studies which have been performed have involved obstetric patients. However, there has been concern over the use of vasopressors in obstetric practice, particularly methoxamine, which may decrease uteroplacental blood flow [53]. A possible added complication is the development of severe hypertension if prophylactic vasopressors are used in conjunction with oxytocic drugs [5], particularly in a mother with pre-eclampsia or essential hypertension. This is less likely since synthetic oxytocin replaced the pituitary derivative "Pitocin" which may have been contaminated with vasopressin.

Without volume loading or lateral tilt, the incidence of hypotension in Caesarean section under central neural block exceeds 90 % [10] and most studies of vasopressors in obstetric patients include preliminary volume loading of the patient. This makes evaluation of the effect of vasopressors difficult.

Ephedrine is the most commonly used vasopressor. It has direct and indirect mechanisms of action and stimulates both alpha and beta receptors to increase cardiac output, heart rate, systolic and diastolic arterial pressure. Coronary, cerebral and muscle blood flow are increased, while renal and splanchnic blood flow are decreased [69]. Ephedrine was used first in 1927 to counteract hypotension caused by spinal anaesthesia [47], and early administration to prevent a decrease in arterial pressure was advocated, rather than treating hypotension after it had developed. In a double-blind study during Caesarean section under spinal anaesthesia, patients were given crystalloid 1000 ml and an i.m. injection of ephedrine 50 mg or placebo before the block [24]. All patients in the placebo group became hypotensive (*in spite of the volume load*), compared with only 25 % in the ephedrine-treated group. An increase in systolic arterial pressure occurred in all the ephedrine-treated patients, but significant hypertension did not develop.

A larger, randomized study of prophylactic i.m. ephedrine in extradural Caesarean section compared placebo and i.m. ephedrine 25 mg or 50 mg after volume loading with 1000 ml of crystalloid. The incidence of hypotension was less in this study (8–12 %) and was similar in all the groups. Persistent hypertension was observed in 66 % of the group given ephedrine 50 mg and the study was discontinued for this reason [59].

In non-obstetric patients, development of hypotension is related to the general physical condition of the patient. Patients in ASA grades I–III undergoing spinal anaesthesia for lower body surgery and preloaded with isotonic saline–glucose solution 7 ml kg^{-1} received either placebo or ephedrine 12.5 mg i.v. + 37.5 mg i.m. [26]. No patient given ephedrine became hypotensive, but in the control groups hypotension occurred in 0 %, 12.5 % and 50 % of patients graded ASA, I, II and III, respectively.

I.m. injections of ephedrine before central neural block have unpredictable absorption and peak effect, and do not reliably prevent hypotension. In addition, large bolus doses may cause unacceptable hypertension, so it may be preferable to await the onset of hypotension and then to administer treatment. In a non-random study during Caesarean section with spinal anaesthesia, patients were given crystalloid 1500 ml and allocated to three groups after the block. The control group were those in whom no decrease in arterial pressure occurred (37 %). The remainder were treated with either bolus doses of ephedrine when systolic pressure decreased to less than 100 mm Hg, or as soon as any decrease in arterial pressure from baseline was observed. Episodes of nausea and vomiting caused by hypotension were significantly less frequent in the patients treated early [17].

Vasopressor therapy may be adjusted to the degree of hypotension using an infusion. In a study during Caesarean section with spinal anaesthesia, patients received volume loading with Ringer's lactate solution 15 ml kg^{-1} and were treated with either ephedrine 20 mg i.v. followed by 10-mg doses if arterial pressure decreased to 80 % of baseline, or with ephedrine 10 mg i.v. followed by an infusion of ephedrine adjusted to maintain systolic pressure at 90–105 % of baseline [29]. Total ephedrine dosage was similar in the two groups, but nausea was more frequent in the bolus group (36 %) than in the infusion group (5 %).

Etilefrine (ethyl-norphenylephrine), used in central Europe and Scandanavia, was compared with ephedrine in a randomized study in elderly patients undergoing hip surgery with spinal anaesthesia. Preliminary fluid administration was small, and all patients whose mean arterial pressure decreased by at least 25 % were included in the study. Hypotension was treated with repeated i.v. bolus doses of vasopressor. Both were equally effective in restoring systolic pressure, but ephedrine was more effective in restoring mean and diastolic arterial pressures [66].

Methoxamine acts on alpha receptors to cause peripheral vasoconstriction, with reflex slowing of heart rate [69]. In a retrospective study of Caesarean section under spinal anaesthesia with non-standardized volume loading and no lateral positioning, patients were given prophylactic ephedrine 50 mg, methoxamine 10–12 mg or no vasopressor [44]. Hypotension still occurred in a significant percentage of the patients in both treated groups, and postpartum hypertension in 8 % of the methoxamine group, compared with only 0.8 % in the ephedrine group. A subsequent study showed that methoxamine was associated with a significant risk of decreased uterine perfusion and its use is no longer advocated in obstetric patients [53], although it may have a role in the extreme situation of severe hypotension unresponsive to other methods, especially if the patient has tachycardia.

Phenylephrine has alpha effects identical to those of methoxamine, but also has some weak beta effects and is normally given by infusion [69]. Bolus i.v. administration of phenylephrine 100 µg has been compared with ephedrine 5 mg in the prevention of hypotension during extradural block for Caesarean section after a preload with Ringer's lactate solution 1200 ml [54]. Both drugs were equally effective. Care is required if phenylephrine is given after ephedrine, or in doses greater than 100 µg per bolus. Two cases of overdose resulting in extreme hypertension and headache have been reported, and a recommendation made that no more than 20–40 µg should be given [67].

Dihydroergotamine is a partial alpha agonist which constricts capacitance vessels only and increases systemic vascular resistance in areas subjected to sympathetic block [52]. (In greater doses it also caused prolonged and forceful uterine contraction.) In a study of non-pregnant patients undergoing extradural anaesthesia, volume loading was with crystalloid 2000–3000 ml, and patients were randomized to receive either placebo or dihydroergotamine 0.5 mg by i.v. injection [43]. There was no difference in systolic arterial pressure between the groups and the authors comment that a larger dose might have been more effective.

Mephentermine has direct and indirect sympathomimetic actions which increase cardiac contraction and venous tone and hence increase arterial pressure. It has a prolonged action (4 h) after i.m. injection [69]. Mephentermine has been studied in patients having transurethral prostatectomy under spinal anaesthesia using a variety of local anaesthetic agents and doses [16]. There were four groups of patients who received a preload of 5 % glucose 500 ml, mephentermine 30 mg i.m., a combination of both, or no treatment. Hypotension occurred in 44 % of both the control and the volume loaded groups, but was significantly reduced, to 24 % by mephentermine and to 4 % with combined therapy.

Metaraminol has direct and indirect alpha effects which produce vasoconstriction which may affect peripheral vessels selectively, thus increasing systolic and diastolic pressures and producing a reflex bradycardia [69]. *Dobutamine* has pure $beta_1$ sympathomimetic effects, increasing the force of myocardial contraction [69]. Metaraminol and dobutamine infusions have been compared in patients having major abdominal surgery under extradural anaesthesia [28]. Both agents increased systemic and pulmonary pressures and cardiac work and appeared to be equally effective in preventing hypotension. Dobutamine was preferred because of its selective action on the heart and lack of effect on total peripheral resistance.

Dopamine, the precursor of noradrenaline, causes vasoconstriction through alpha receptor stimulation when used in large doses [69], and it may be an ideal agent to use in the prevention of hypotension because of its rapid onset and short duration of action. In a study during Caesarean section under spinal anaesthesia, 78 % of the patients became hypotensive and were allocated randomly to receive an infusion of dopamine 2–10 µg kg^{-1} min^{-1} or i.v. boluses of ephedrine 10 mg [9]. The remaining 22 % of patients who did not show any decrease in arterial pressure formed the control group. Although dopamine proved effective, it was no more so than intermittent ephedrine. Dopamine 4 µg kg^{-1} min^{-1} has been shown to increase mean arterial pressure, cardiac output and heart rate during thoracic extradural anaesthesia in which volume loading with 5 % albumin 500 ml with crystalloid 1000 ml was not effective in preventing hypotension [37].

Adrenaline is a potent alpha and beta stimulator. Its predominant effect is to increase systolic pressure by direct myocardial stimulation, increased heart rate and vasoconstriction in the skin, mucosa and kidneys [69]. In a study in anaesthetized, splenectomized sheep, extradural analgesia was performed and decreases in arterial pressure and peripheral resistance were observed. Administration of Dextran 70, 10 mg kg^{-1} produced a small increase in arterial pressure secondary to increased stroke volume, but this was counteracted by a further decrease in total peripheral resistance. Administration of adrenaline approximately 1 $\mu g\ kg^{-1}\ min^{-1}$ reversed the hypotension by increasing cardiac output secondary to improved contractility and venous return. There was no effect on peripheral resistance [49]. This study showed that plasma expansion alone was insufficient to counteract systemic hypotension, but that adrenaline can restore arterial pressure without adverse effects on regional perfusion. In elderly patients undergoing total hip replacement with hypotensive extradural anaesthesia, low dose adrenaline infusion was used effectively to maintain arterial pressure at 50–55 mm Hg, by increasing cardiac index and stroke volume without change in heart rate [61].

Prenalterol, a $beta_1$ receptor agonist has been used in a small study of thoracic extradurals for aortic aneurysm surgery. Hypotension occurred in all patients and was treated with prenalterol 10 mg by i.v. infusion. Arterial pressure was rapidly restored as a result of increased cardiac output without any increase in heart rate or vascular resistance [57].

SUMMARY

Hypotension during central neural block may occur by three main mechanisms: decrease in venous return (in turn influenced by posture, bleeding and inferior vena cava compression), vasodilatation and decreased cardiac output. It is also important to recognize that, occasionally, other factors play a part. Bladder distension during central nerve block has been shown to produce hypotension inappropriate to the level of block [48, 62] and vagal overactivity may contribute in the unsedated patient. Preventive measures to reduce the likelihood of hypotension include correction of hypovolaemia, restriction of the upper level of block, use of a slight head-down tilt to maintain venous return and judicious use of sedation, especially in anxious patients. In the obstetric patient, the single most important factor in eliminating hypotension is the use of full left-lateral tilt. Mechanical methods to improve venous return by compressing the legs are not particularly helpful. Volume loading does not guarantee maintenance of arterial pressure and excessive fluid may be harmful in patients with bladder neck obstruction or at risk of pulmonary oedema. The administration of up to 1 litre before surgery may be particularly advisable if significant blood loss is expected (no matter what the anaesthetic technique), but colloid solutions do not have clear proven benefit over crystalloid.

The prevention or treatment of hypotension induced by central block by administration of large volumes of fluid is a more contentious subject, although the practice is widespread. Review of the literature has shown that many studies have been poorly designed and the results have often been contradictory, even in such basic principles as the incidence of hypotension in control groups. There is a need for evidence based on correctly designed studies comparing tightly designed treatment regimens. One such study [72] has recently shown the benefit of ephedrine compared with both volume loading and methoxamine in the prophylaxis of cardiovascular changes during combined extradural and general anaesthesia. In the treatment of hypotension, vasopressors can be much more rapidly effective and directly reverse the physiological changes produced by the block. Early intervention with small i.v. doses (e.g. ephedrine 3–6 mg or methoxamine 1–2 mg) if arterial pressure decreases towards an unacceptable value provides better control than large i.m. doses given before the block. Finer control can be achieved by using a suitable drug in an infusion. Ephedrine is probably the most useful drug in terms of safety and efficacy, but a drug with predominantly alpha agonist activity (e.g. methoxamine) may be more appropriate if heart rate is increased, especially if the response to ephedrine is poor. The decision on *what* degree of hypotension requires treatment can be made only for individual patients, but there are few who cannot tolerate a decrease of 25–30% quite safely.

SHORT COMMUNICATIONS

HAEMODYNAMIC CHANGES IN PATIENTS UNDERGOING LAPAROSCOPIC CHOLECYSTECTOMY: MEASUREMENT BY TRANSTHORACIC ELECTRICAL BIOIMPEDANCE

L. A. H. CRITCHLEY, J. A. J. H. CRITCHLEY AND T. GIN

SUMMARY

Using transthoracic electrical bioimpedance with the BoMed NCCOM3-R7, we measured cardiovascular changes in 16 ASA I and II Chinese patients undergoing laparoscopic cholecystectomy. The peritoneal cavity was insufflated with carbon dioxide to a pressure up to 15 mm Hg. Tidal volume, minute volume and end-tidal carbon dioxide partial pressure were kept constant. Insufflation resulted in a mean (SD) 13 (14)% decrease in stroke index (SI) ($P < 0.01$), but the effect on cardiac index (CI) was more variable (mean 7 (17)% decrease, range 36% decrease to 22% increase ($P = 0.07$)). Mean arterial pressure increased by 55 (29)% ($P < 0.001$) and systemic vascular resistance index increased by 63 (33)% ($P < 0.001$), with the maximum effect occurring 10–15 min after the commencement of insufflation. Multiple regression analysis showed a greater decrease in SI in patients with a small body mass index and large intraperitoneal pressure ($P = 0.01$), while a greater decrease in CI was found in patients with a small body mass index and younger age ($P = 0.001$). Three patients had a further reduction in CI during surgery, with one patient having a 48% decrease compared with pre-induction values. Deflation of the peritoneum resulted in an increase in both CI (25 (26)%) and (22 (29)%) ($P < 0.01$) to values which were not different from pre-induction data. Arterial blood-gas analysis showed decreases in pH and base excess after 1 h of insufflation ($P < 0.01$). (Br. J. Anaesth. 1993; **70**: 681–683)

KEY WORDS

Measurement techniques: transthoracic electrical bioimpedance. Surgery: laparoscopic cholecystectomy.

During laparoscopic gynaecological surgery, insufflation of the peritoneal cavity is usually tolerated well and causes a moderate decrease in cardiac output and an increase in mean arterial pressure [1, 2]. During laparoscopic cholecystectomy, these cardiovascular changes may be greater and more significant because head-up tilt is commonly used, a prolonged period of insufflation is often required and the patients are older, with less cardiopulmonary reserve [3]. We have measured cardiac output non-invasively during laparoscopic cholecystectomy using the BoMed NCCOM3-R7 (BoMed Medical Manufacturing Ltd, Irvine, CA, U.S.A.), which measures beat-to-beat stroke volume using changes in transthoracic electrical bioimpedance [4].

METHODS AND RESULTS

Local Ethics Committee approval and informed consent were obtained. Data were collected from nine male and seven female ASA I or II Chinese patients.

Diazepam 5–10 mg was given 1 h before surgery. Anaesthesia was induced with thiopentone 3–5 mg kg^{-1} and maintained with 0.5% isoflurane and 70% nitrous oxide in oxygen and fentanyl 2–5 µg kg^{-1}. Atracurium was given to facilitate tracheal intubation and maintain neuromuscular block. Normal saline was given i.v. at 5 ml kg^{-1} h^{-1}. The lungs were ventilated with a tidal volume of 10 ml kg^{-1} at 10 b.p.m. End-tidal carbon dioxide partial pressure (PE'_{CO_2}) was maintained at 5.3 kPa using a circle system and varying the gas flow through the carbon dioxide absorber. Fifteen minutes after induction of anaesthesia, the peritoneal cavity was insufflated with carbon dioxide and maintained at a pressure of 11–15 mm Hg throughout the procedure.

The mean arterial pressure (MAP) was measured every 1–3 min (Dinamap 1846SX). The BoMed was connected to the patient using four neck and four lower thoracic electrodes [4]. Stroke index (SI), cardiac index (CI) and heart rate (HR) were recorded continuously. All data were averaged over 16 beats and stored on an IBM-compatible lap-top computer. A 22-gauge radial artery catheter was inserted and blood-gas analysis performed after induction of anaesthesia, after insufflation and at 30-min intervals throughout the procedure. The peak airway pressure, PE'_{CO_2} and intraperitoneal pressure were recorded before and after insufflation, at 10-min intervals during the procedure and after deflation of the peritoneal cavity. Central venous pressure was measured in one patient. Values of 3 mm Hg before induction, 4 mm Hg before insufflation, 10 mm Hg after insufflation and 4 mm Hg after deflation were

used as the best estimate of right atrial pressure (RAP) in the calculation of systemic vascular resistance index (SVRI), where SVRI = 79.9 (MAP − RAP)/CI (dyn s cm^{-5} m^{-2}). Errors in this approximation are small and cause only a small percentage change in (MAP − RAP) and hence SVRI.

The procedure was divided into five stages: awake (5-min period before induction of anaesthesia); anaesthetized (5-min period before insufflation); insufflated (5-min period starting 5 min after insufflation); laparoscopic surgery (20 min after starting insufflation to deflation); deflated (5-min period after deflation). In every patient, the mean values for CI, SI, HR, MAP and SVRI were calculated for each stage. Consecutive means for the five stages were compared using a paired *t* test. Serial arterial blood-gas analysis results were compared by a Wilcoxon signed rank test. The percentage change between the anaesthetized and fully insufflated stages for SI and CI were compared with age, body mass index (BMI = body weight divided by the square of height), peak airway pressure and intraperitoneal pressure using multiple stepwise regression. $P < 0.05$ was considered significant. Results are presented as mean (SD).

The patients were aged 32–78 yr, weights 33–72 kg, heights 141–180 cm and BMI 16.6–25.4 kg m^{-2} (normal range: 19–24 kg m^{-2}).

Induction of anaesthesia caused decreases in CI, HR and MAP (table I). Peak airway pressure was in the range 11–22 cm H_2O (median 17.0 cm H_2O) before insufflation and 13–38 cm H_2O (median 21.5 cm H_2O) during insufflation. Insufflation resulted in a 13 (14)% decrease in (SI), a 55 (29)% increase in MAP and a 63 (33)% increase in SVRI (all $P < 0.01$), but the effect on CI was more variable, ranging from a 36% decrease to a 22% increase. A peak in MAP was seen in all 16 patients, 10–15 min after insufflation and before intraperitoneal surgery started.

The duration of insufflation was 24–130 min (median 55 min). Although CI increased usually during surgery, three patients had a further 15–20% reduction in CI. Deflation was followed by a 25 (26)% increase in CI, a 22 (29)% increase in SI and a 20 (16)% decrease in SVRI (all $P < 0.01$) to values which were not different from the awake values.

Multiple regression analysis showed a greater decrease in SI in patients with a small BMI ($P = 0.005$) and large intraperitoneal pressure ($P = 0.04$) ($r = 0.71$, $P = 0.01$) and a greater decrease in CI in patients with a small BMI ($P = 0.002$) and younger age ($P = 0.007$) ($r = 0.81$, $P = 0.001$).

Progressive acidosis was observed in all patients (table II). PE'_{CO_2} underestimated arterial blood carbon dioxide tension (Pa_{CO_2}) by an average of 0.7 kPa.

One patient, a 33-kg female with untreated hypertension and chronic bronchitis, had a 48% decrease in SI and CI after insufflation compared with awake values. Although insufflation only lasted 24 min, arterial blood-gas analysis at this time showed pH = 7.23, Pa_{O_2} = 26.9 kPa, Pa_{CO_2} = 7.8 kPa and base excess = −3.4 mmol $litre^{-1}$.

COMMENT

The SI decreased with insufflation and multiple regression analysis suggested that increased intra-abdominal pressure was a contributing factor. A detailed study in dogs by Ivankovich [5] showed the decrease to be related to reduced inferior vena cava blood flow. However, increased intrathoracic pressure causing cardiac tamponade and the redistribution of splanchnic blood reserves [2] have also been suggested as possible aetiologies.

The effect of insufflation on CI was less consistent. Motew and colleagues [2] suggested that, in addition to the increased intra-abdominal pressure, other opposing physiological effects such as systemic carbon dioxide uptake and surgical stimulation may be involved.

The increases in MAP and SVRI appeared to be independent of systemic carbon dioxide absorption and surgical stimulation because the maximum increase occurred 10–15 min after insufflation. In dogs, insufflation with nitrous oxide has haemodynamic affects similar to those of carbon dioxide [5]. Patients with massively increased intra-abdominal pressure show similar changes [6]. The increases in MAP and SVRI may be a result of a reflex increase in systemic vascular resistance in response to abdominal distention.

We found that patients with a small BMI experienced a greater decrease in SI and CI after insufflation. This is difficult to interpret and further studies are needed to define which patients are more susceptible to the haemodynamic effects of insufflation.

A progressive, mild metabolic acidosis was noted in all patients and was more marked after only 24 min of insufflation in the patient with a 48% decrease in CI. Similar cases have been reported [1, 3]; in one [3], laparoscopy was aborted after failed attempts to correct the acidosis by increasing ventilation. The acidosis may have been caused partly by a decreased cardiac output with decreased peripheral perfusion and it is possible that increasing ventilation may have depressed cardiac output further. Routine intra-operative monitoring failed to provide evidence of these complications.

We found haemodynamic changes similar to those reported in gynaecological laparoscopy. However, the physiological effects of laparoscopic cholecystectomy appear to be greater.

ALTERATIONS IN PAIN THRESHOLD AND PSYCHOMOTOR RESPONSE ASSOCIATED WITH SUBANAESTHETIC CONCENTRATIONS OF INHALATION ANAESTHETICS IN HUMANS

K. TOMI, T. MASHIMO, C. TASHIRO, M. YAGI, M. PAK, S. NISHIMURA, M. NISHIMURA AND I. YOSHIYA

SUMMARY

*We studied the effects of six inhalation anaesthetics at subanaesthetic concentrations of 0.2 MAC on pain threshold and psychomotor function in six healthy volunteers. When compared with 100% oxygen inhalation, nitrous oxide and methyoxyflurane significantly increased pain threshold as measured by a radiant heat algometer, and prolonged the response time to auditory stimuli. In contrast, halothane, enflurane, isoflurane and sevoflurane produced prolongation of the response time to auditory stimuli but did not influence pain perception. The pain threshold with nitrous oxide remained significantly increased 30 min after its discontinuation, while the response time returned to the preinhalation value. We conclude that nitrous oxide and methoxyflurane possess both analgesic and hypnotic actions but halothane, enflurane, isoflurane and sevoflurane do not have an analgesic action at subanaesthetic concentrations, and the analgesic action of nitrous oxide persists after its elimination. (*Br. J. Anaesth. 1993; **70**: 684–686)

KEY WORDS

Anaesthetics, gases: nitrous oxide. Anaesthetics, volatile: methoxyflurane, halothane, enflurane, isoflurane, sevoflurane. Analgesia.

General anaesthesia is a result of both analgesic and hypnotic actions of an anaesthetic agent or a combination of hypnotic and analgesic agents. There has been no study to differentiate the analgesic potency from hypnotic potency of inhalation anaesthetics, because there is no way of differentiating both properties in the anaesthetic concentration range. Although some anaesthetic agents have been demonstrated to cause an increase in pain threshold in subanaesthetic concentrations [1–3], there has been no report that simultaneously evaluated both analgesic and hypnotic actions of inhalation anaesthetics. Therefore, we studied six currently available inhalation anaesthetics at subanaesthetic concentrations in terms of their effects on pain threshold and psychomotor function in normal volunteers.

METHODS AND RESULTS

The study was approved by the Medical Ethics Committee of Osaka University Medical School.

We studied six healthy male volunteers (mean age 37.4 yr, range 29–51 yr; weights 68.3 (SD 13.7) kg) after obtaining informed consent. Each subject was exposed to 100% oxygen and six inhalation anaesthetics at 7-day intervals. The subjects lay comfortably in a supine position for at least 10 min before measurements were made. The anaesthetic gases and oxygen were delivered via an anaesthetic circuit and face mask. End-tidal concentrations of anaesthetics and carbon dioxide were monitored using a Capnomac (Datex). The assessments of analgesic and hypnotic effects were undertaken using 20 trials of the psychomotor test, 25 trials of the pain threshold test and then 20 trials of the psychomotor test. Control, baseline measurements were made while the subject was breathing air via an anaesthetic circuit. After 10 min, one of the following anaesthetics diluted in oxygen 8–10 litre min^{-1} was administered to the subject: methoxyflurane, halothane, isoflurane, enflurane, sevoflurane, nitrous oxide. The end-tidal concentration of each anaesthetic was adjusted to 0.2 MAC equivalent. After the end-tidal concentration was maintained at this value for 20 min, measurements were repeated at the same anaesthetic concentration. Seven series of experiments were performed in random order in a single subject with the six different anaesthetics, plus a control experiment using 100% oxygen.

Pain threshold was assessed using an improved radiant heat algometer (Nakahama Pain Meter NYT-55 (Kudo Electric)) [4]. The thermal output of the algometer was stabilized at a precision of ±1% using a power feedback mechanism. The surface temperature at the site of measurement was maintained constant at 36.5 °C. Five circular sticky tapes

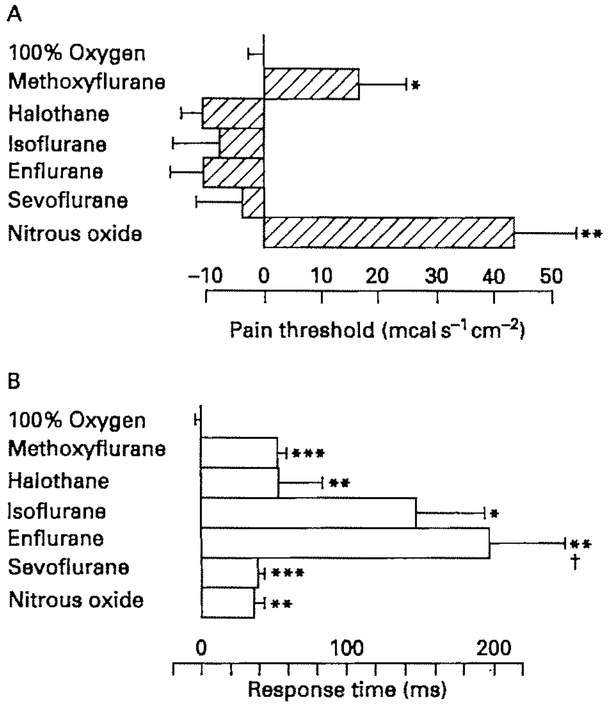

FIG. 1. Differences between values of pain threshold (A) and response time to auditory stimuli (B) measured while the subject breathed air or inhaled oxygen or anaesthetic gases at 0.2 MAC equivalent ($n = 6$) (mean, SE). A: $^{**}P < 0.01$ compared with 100% oxygen, halothane, isoflurane, enflurane and sevoflurane. $^{*}P < 0.05$ compared with 100% oxygen and halothane. B: $^{*}P < 0.05$, $^{**}P < 0.01$, $^{***}P < 0.001$ compared with 100% oxygen; $^{\dagger}P < 0.05$ compared with methoxyflurane, halothane, sevoflurane and nitrous oxide.

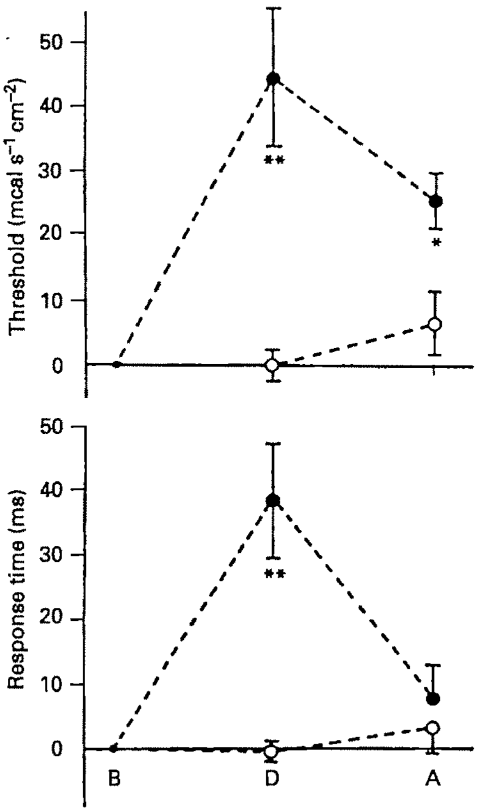

FIG. 2. Mean (SE) residual effects of nitrous oxide on pain threshold and response time ($n = 6$): changes from value before inhalation (B). D = During inhalation; A = 30 min after discontinuation of 100% oxygen (○) or 21% nitrous oxide (●). $^{*}P < 0.05$; $^{**}P < 0.01$ compared with 100% oxygen.

painted black on each side and 18 mm in diameter were stuck to the proximal region of the forearm skin surface. These black spots were subjected, in order, to thermal stimulation by the metal plate of a stimulation head. Pain threshold was determined from the response to thermal stimuli of 3 s duration using the "up-and-down" method [5]: the first stimulus carried a thermal energy of 300 $\mathrm{mcal\ s^{-1}\ cm^{-2}}$; the thermal energy was increased if the stimulus did not cause pain, or decreased after pain. Heat energy was increased or decreased in 20-mcal steps until the sixth exposure, and in 10-mcal steps from the seventh. Heat stimuli were given 25 times at 40-s intervals.

The time elapsed from an auditory stimulus to striking the space key of a personal computer (Nihon Electric Company Ltd, PC 9801 VX) was defined as the response time. The auditory signal was generated by the computer in a random fashion. The frequency of the signal sound used was 1000 Hz and the intervals between sounds varied in the range 1–10 s. Measurements were made 20 times before and 20 times after the pain threshold test. The average value of 40 trails was taken as the response time.

When a subject was given nitrous oxide, additional measurements were performed 30 min after discontinuation of nitrous oxide in oxygen in order to examine any residual effects of the agent.

For statistical analysis, one-way analysis of variance with repeated measures, Dunnett's T test and Tukey's Studentized Range test were used. $P < 0.05$ was considered significant.

Pain thresholds after methoxyflurane and nitrous oxide were significantly greater than in the control group (100% oxygen) (16.3 (23.8) $\mathrm{mcal\ s^{-1}\ cm^{-2}}$ ($P < 0.05$) and 44.2 (27.9) $\mathrm{mcal\ s^{-1}\ cm^{-2}}$ ($P < 0.01$), respectively) (fig. 1A). With the other anaesthetics, pain thresholds did not differ significantly from that in the control group. The pain threshold with nitrous oxide was significantly greater than those with all other anaesthetics tested ($P < 0.01$), with the exception of methoxyflurane. The pain threshold with methoxyflurane was significantly greater than with halothane group ($P < 0.01$).

The response time was increased with all anaesthetics compared with oxygen ($P < 0.01$) (fig. 1B). It was significantly longer with enflurane than with any other anaesthetic, with the exception of isoflurane. With both enflurane and isoflurane, the subjects felt sleepy and three of the subjects intermittently fell asleep.

When tested 30 min after discontinuation of nitrous oxide, the pain threshold remained increased (24.6 (10.7) $\mathrm{mcal\ s^{-1}\ cm^{-2}}$, compared with 6.4 (11.8) $\mathrm{mcal\ s^{-1}\ cm^{-2}}$ with oxygen ($P < 0.05$)) (fig. 2). In contrast, psychomotor reaction time returned to the air-breathing value 30 min after discontinuation of nitrous oxide. There was no significant difference in response time between nitrous oxide (7.6 (13.6) s) and oxygen (3.1 (9.6) s) at this time (fig. 2).

COMMENT

Since the earliest study by Dundee and Moore [1], there have been several studies on analgesic actions of anaesthetic agents. Our data on nitrous oxide correspond well with results reported previously, but our data for methoxyflurane and halothane do not [1–3]. This is the first report on sevoflurane which suggests a lack of analgesic effect.

We found no differences in psychomotor response times when we compared anaesthetic agents with (methoxyflurane and nitrous oxide) and without (halothane and sevoflurane) analgesic property. We also found that enflurane reduced significantly greater response times than halothane or sevoflurane. These data suggest that hypnotic and analgesic properties are MAC determinants, but that the dose–effect relationship is strictly non-linear in terms of hypnotic or analgesic properties, and as a consequence, hypnotic and analgesic data determined, at sub-anaesthetic concentrations of inhalation anaesthetics cannot be extrapolated to MAC values.

We have shown that the analgesic action of nitrous oxide persists after its elimination from the body. This indicates that some analgesic substances may be produced by nitrous oxide *in vivo*. Berkowitz, Ngai and Finck [6] demonstrated that nitrous oxide produced dose-related analgesia and that opioid antagonists reduced its analgesic action in mice. They speculated that nitrous oxide could release endorphins or activate endorphin systems in the central nervous system.

Our data showing no residual effect of nitrous oxide on psychomotor response confirm the results reported by Korttila and colleagues [7], who also found no evidence of tolerance developing to the psychomotor effects of nitrous oxide.

ADRENALINE-INDUCED HYPOTENSION IN NEUROSURGERY

S. PHILLIPS, S. E. HUTCHINSON, P. BAYLY AND T. E. HOLLWAY

SUMMARY

We have compared the effects of scalp infiltration with 0.5% lignocaine, 0.5% lignocaine with adrenaline 1:200000, 0.9% saline and 0.9% saline with adrenaline 1:200000, in a prospective, randomized, double-blind study. Direct arterial pressure, heart rate and bleeding at incision were recorded in 80 patients undergoing craniotomy or craniectomy. Arterial pressure decreased by more than 20% from preinfiltration values in 40% of patients in the saline with adrenaline group, and in 55% of patients in the lignocaine with adrenaline group. It did not decrease in patients who did not receive adrenaline. (Br. J. Anaesth. 1993; **70**: 687–688)

KEY WORDS

Anaesthesia: neurosurgical. Complications: cardiovascular responses. Sympathetic nervous system: beta-adrenergic agonists, subcutaneous adrenaline.

Cerebral perfusion pressure equals mean arterial pressure minus intracranial pressure. In the normal brain, blood supply is maintained constant over a wide range of arterial pressure because of autoregulatory mechanisms [1, 2]. Many neurosurgical patients have increased intracranial pressure and require an increased arterial pressure to ensure cerebral perfusion. Indeed, in those patients whose cerebral autoregulatory mechanisms have been inactivated by disease, cerebral perfusion is dependent on arterial pressure.

In order to reduce bleeding from the scalp and obtund the response to surgical incision, many neurosurgeons routinely infiltrate the subgaleal layer with local anaesthetic and vasoconstrictor; in our institution, 0.5% lignocaine with adrenaline 1:200000 is used. It was noticed that, after this infiltration, a large decrease in arterial pressure occurred, frequently without any change in heart rate. This is in contrast with the hypertensive effect reported previously when solutions containing adrenergic compounds were used [3–5]. The cause for this hypotension, occurring at a relatively uneventful and predictable time during the procedure, was not obvious.

Although the significance of this period of hypotension is unclear, it is conceivable that, in a patient with critical cerebral perfusion, any reduction in arterial pressure may result in cerebral ischaemia. This study was designed to determine which component of the infiltration solution was responsible for hypotension, the frequency and severity of the hypotension, and the effect of different solutions on scalp bleeding.

METHODS AND RESULTS

The study was approved by the Local Medical Ethics Committee and written informed consent was obtained from each patient. We studied 80 neurosurgical patients, aged more than 15 yr and scheduled to undergo craniotomy or craniectomy. The solution used for scalp infiltration was allocated randomly to each patient: group A = 0.9% saline with adrenaline 1:200000 (freshly prepared); group B = 0.5% lignocaine (Antigen); group C = 0.5% lignocaine with adrenaline 1:200000 (Astra); group D = 0.9% saline (Antigen). Neither the anaesthetist nor the surgeon was aware of which solution was used.

All patients received glycopyrronium 0.3 mg i.m. 1 h before operation. Anaesthesia was induced with thiopentone 4–5 mg kg^{-1} and fentanyl 5–10 μg kg^{-1}. Neuromuscular block was produced with vecuronium 0.2 mg kg^{-1} and maintained by infusion. The lungs were ventilated with 66% nitrous oxide and 0–1% isoflurane in oxygen using a Cape Waine ventilator. End-tidal carbon dioxide partial pressures were maintained at 3.5–4.2 kPa. Immediately after induction of anaesthesia, a 20-gauge cannula was inserted into a radial artery and direct arterial pressure measurement commenced using a transducer (Medex) and Cardiocap (Datex) monitor. This was in turn connected to a TOA pen recorder with a paper speed of 20 mm min^{-1}. The transducer and chart recorder were calibrated against a mercury manometer before each use. After transfer to the operating table and a period of haemodynamic stability, the patient was prepared and the scalp infiltrated. The volume of infiltrate used (never more than 20 ml) was at the discretion of the surgeon and thus reflected clinical practice. A hard copy of the arterial pressure trace was made for 2 min before infiltration and continued for a further 5 min.

After raising the skin flap, the surgeon assessed the degree of bleeding as 1 = nil, 2 = minimal, 3 = average, 4 = more than normal, 5 = unacceptable.

At a later date, the arterial pressure traces were assessed from the hard copy by an observer who was unaware of which solution had been used. The systolic and diastolic arterial pressures were noted and the mean arterial pressure calculated ([(systolic − diastolic)/3] + diastolic) every 15 s. The arterial pressure for the 2 min before infiltration was averaged and the number of patients exhibiting a decrease of more than 20% from this value was calculated for each group.

Results for arterial pressure changes were compared using the chi-square test. The effect of adrenaline on bleeding scores was compared using the chi square-test for trend. Patient characteristics and baseline cardiovascular variables were similar in all groups (table I).

A decrease of at least 20% in arterial pressure from values before infiltration occurred in a mean 47.5% of patients receiving adrenaline (groups A and C) and 2.5% of those who did not ($P < 0.001$) (table II). Two patients in group A and two in group C had a decrease of more than 30% from the baseline. The largest reduction (36%) occurred in a patient who had received lignocaine with adrenaline, but there was no significant difference in arterial pressure decrease between groups who did (B, C) or did not (A, D) receive lignocaine ($P = 0.3$).

The average time from infiltration to the smallest recorded pressure was 124 s; mean duration of the trough was 92 s. Heart rate did not vary by more than 10% from baseline in any group, and was similar in all groups.

Bleeding scores as reported by the surgeon were smaller in groups A and C, who received adrenaline ($P < 0.01$) (table III).

COMMENT

Our study has demonstrated that s.c. infiltration of the scalp with solutions containing 1:200000 adrenaline can cause arterial pressure to decrease by more than 20% of baseline values in 47.5% of patients. No change in heart rate occurred. Solutions containing adrenaline reduced surgical bleeding at incision.

It is well known that adrenaline is one of the most potent vasopressors [6] and previous work has been concerned with an increase in arterial pressure [4, 5] associated with its use. It is well known also, however, that small doses of adrenaline (0.1 $\mu g\ kg^{-1}$) may cause the arterial pressure to decrease [6] because of greater sensitivity to adrenaline of vasodilator beta_2 receptors, especially in skeletal muscle beds, than alpha_1 constrictor receptors.

Other possible explanations for the decrease in arterial pressure are unlikely. Myocardial depression by anaesthetic drugs, or vagal response to stretching of the galea, for example, should also have occurred in the saline and lignocaine groups. We did not attempt to relate the dose of adrenaline to body weight, regulate the speed of injection or measure blood concentrations of adrenaline, therefore we cannot say if the effect was dose- or time-related.

Many neurosurgical patients have abnormal cerebral autoregulation and depend on adequate mean arterial pressure for cerebral perfusion. In these patients, a period of hypotension (in our patients for a mean of 92 s) could result in cerebral ischaemia and is undesirable.

SHUNT FLOW AND CAVAL PRESSURE GRADIENT DURING VENO–VENOUS BYPASS IN HUMAN ORTHOTOPIC LIVER TRANSPLANTATION

R. U. SCHERER, R. M. GIEBLER, M. J. SCHMUTZLER, F. M. GÜNNICKER AND W. J. KOX

SUMMARY

The routine use of veno–venous bypass during the anhepatic phase of orthotopic liver transplantation is controversial. Decreased shunt flows (1.5–3.0 litre min^{-1}), as reported in the literature, may explain the lack of beneficial effects on outcome. We have studied the influence of bypass flows on caval pressure gradient (CPG) and renal perfusion pressure (RPP) in 45 patients undergoing orthotopic liver transplantation using a portofemoro–subclavian veno–venous bypass system. Mean shunt flow was 3.63 litre min^{-1}. Second-order polynomial regressions best described the relationship between shunt flow and CPG ($r = 0.674$), RPP ($r = 0.727$), and cardiac output ($r = 0.602$). Shunt flows less than 3.0 litre min^{-1} failed to normalize CPG and RPP, whereas flows greater than 5.0 litre min^{-1} did not substantially improve haemodynamic state. (Br. J. Anaesth. 1993; **70**: 689–690)

KEY WORDS

Liver: blood flow. Surgery: Liver transplantation.

There is no evidence that extracorporeal veno–venous bypass during orthotopic liver transplantation is beneficial [1] as far as outcome is concerned [2]; however, improvement in such physiological variables as cardiac output and urine production has been demonstrated [2].

Shunt flows described in the literature range from 1.5 to 3.0 litre min^{-1} in adults [2–4]. It is not known if such flows are sufficient to normalize haemodynamic pressures and thus cardiac output. Therefore, we have assessed the efficacy of shunt flow during portofemoro–subclavian bypass by measuring infra- (ICAVP) to suprahepatic (SCAVP) caval pressure gradient (CPG) and mean arterial pressure (MAP), from which renal perfusion pressure (RPP = MAP − ICAVP) was derived.

METHODS AND RESULTS

After obtaining local Ethics Committee approval and written, informed consent, we studied the efficacy of portofemoro–subclavian bypass in 45 consecutive adult patients (23 male) undergoing elective or emergency orthotopic liver transplantation. Adults with a body weight less than 50 kg were excluded. Median age was 42 yr (range 19–65 yr) and median body surface area 1.84 m^2 (range 1.34–2.28 m^2). Thirty patients were classified Child B, and 15 Child C; nine were "high urgent" (Eurotransplant urgency code HU) because of fulminant hepatic failure.

General anaesthesia was maintained by a continuous infusion of propofol 40–60 μg kg^{-1} min^{-1} and fentanyl 0.1–0.3 μg kg^{-1} min^{-1} with 0.4–0.6% isoflurane. Fluid administration, blood transfusion and catecholamine support were adjusted to produce a normal haemodynamic state with a mean arterial pressure > 60 mm Hg, central venous pressure 5–10 mm Hg, cardiac index > 2.5 litre min^{-1} m^{-2}, haemoglobin concentration 10 g litre^{-1} and PCV 30%. All patients received low-dose dopamine 3–5 μg kg^{-1} min^{-1}. In six urgent cases, adrenaline 0.1–0.3 μg kg^{-1} was given to maintain cardiac output. ICAVP was measured via the right femoral vein.

Before operation, the left femoral and subclavian veins were cannulated with 7-mm single lumen catheters (LAUB percutaneous cannulation set, Cook Europe, Mönchengladbach, Germany) for portofemoro–subclavian bypass. Shunt flows were initially rendered optimum by adjusting the pump speed to the greatest possible flow rate before collapse of the tubing.

When shunt flow reached a steady state during the anhepatic phase, haemodynamic measurements were performed. Cardiac index (CI), oxygen transport ($D\text{o}_2$) and oxygen consumption ($\dot{V}\text{o}_2$) were derived using the usual equations. Statistical analysis was performed by linear and second order polynomial regression analysis. The significance of sample correlation coefficient (r) was calculated using a two-tailed t test. $P < 0.05$ was considered significant.

Mean shunt flow was 3.63 (SEM 0.20) litre min^{-1} (range 0–6.6 litre min^{-1}). In one patient it was not possible to establish a shunt flow because of air entrainment into the portal cannula. Mean haemo-

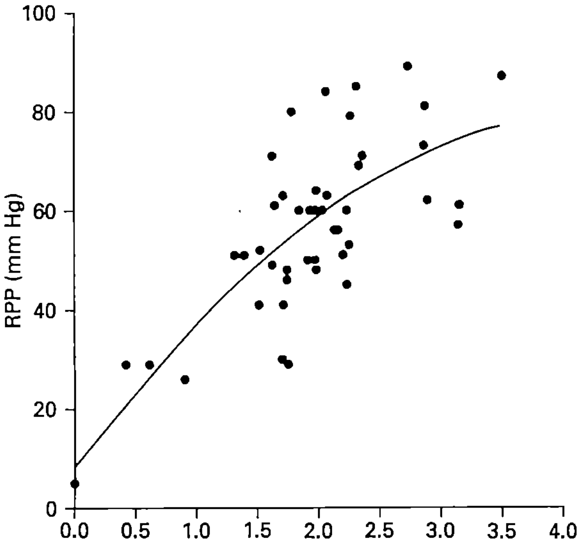

FIG. 1. Relationship between shunt flow index (SFLI) and renal perfusion pressure (RPP): $y = 8.22+32.02x-3.82x^2$. $r = 0.744$, $P < 0.0005$.

globin concentration was 9.9 (1.5) g litre^{-1} before onset of veno–venous bypass and 10.2 (0.26) g litre^{-1} during shunt; PCV was 29.2 (0.69)% and 30.0 (0.98)%, respectively.

During veno–venous bypass, CI was 3.82 (0.16) litre min^{-1} m^{-2} (4.41 (0.2) litre min^{-1} m^{-2} before bypass); MAP was 74.9 (2.3) mm Hg (77.7 (1.9) mm Hg before bypass); CPG was 6.8 (0.8) mm Hg (7.5 (1.2) mm Hg before bypass) RPP was 56.4 (2.7) mm Hg (62.4 (1.9) mm Hg before bypass); PAP was 17.5 (0.7) mm Hg (18.1 (0.9) mm Hg before bypass), PAOP was 8.9 (1.2) mm Hg (11.7 (1.0) mm Hg before bypass); $D\text{O}_2$ was 491.6 (26.7) ml min^{-1} m^{-2} (549.2 (26.5) ml min^{-1} m^{-2} before bypass) and $\dot{V}\text{O}_2$ was 115.7 (7.8) ml min^{-1} m^{-2} (124.3 (3.9) ml min^{-1} m^{-2} before bypass).

The relationship between shunt flow and CPG was characterized best by a second-order polynomial regression ($y = 22.78-7.19x+0.68x^2$; $r = 0.674$, $P < 0.0005$). Taking into account the patient's body surface area by correlating the CPG and RPP to shunt flow index, an even better correlation with CPG ($r = 0.66$, $P < 0.0005$) and RPP ($r = 0.744$, $P < 0.0005$) was found (fig. 1).

As far as the relationship between shunt flow and CPG or RPP was concerned, we found no differences between patients with chronic and acute hepatic failure.

The relationship between shunt flow and $D\text{O}_2$ was characterized by a second-order polynomial regression ($y = 98.11+3.72x-0.13x^2$; $r = 0.329$, $P < 0.05$). ICAVP and $\dot{V}\text{O}_2$ showed an inverse relationship (second-order polynomial regression $y = 38.11+3.72x-0.13x^2$; $r = 0.329$, $P < 0.05$).

COMMENT

Our study has shown that the use of a 7-mm percutaneous cannulation set for catheterization of the subclavian and femoral veins for portofemoro–subclavian bypass ensures large shunt flows (mean 3.6 litre min^{-1}). The data indicate that CPG and hence RPP were dependent on shunt flow and that this relationship was almost linear for a shunt flow less than 3 litre min^{-1}. The correlation between shunt flow and CO ($r = 0.602$, $P < 0.0005$) in our patients was good, as were the correlations between shunt flow and RPP ($r = 0.675$, $P < 0.0005$) or CPG ($r = 0.571$, $P < 0.0005$), respectively. ICAVP and hence CPG and RPP were dependent mainly on shunt flow and thus mirrored the efficacy of blood drainage from the portocaval to the superior caval venous system.

If orthotopic liver transformation is performed without veno–venous bypass RPP is usually small, leading to intraoperative oliguria [1]. Estrin and colleagues [5] found a mean RPP between 40 and 49 mm Hg in 26 adult patients without veno–venous bypass and the CPG was 36–37 mm Hg. In that group of patients, mean arterial pressure during the anhepatic phase was surprisingly increased and even greater (82–98 mm Hg) than in the pre-anhepatic phase (81–91 mm Hg), probably because of fluid and catecholamine administration.

Adverse haemodynamic changes associated with cross clamping of the caval vein can be overcome by volume loading [5] without major complications [1] such as fluid overload. Even with veno–venous bypass, this remains a major problem and has led to the institution of intraoperative continuous arteriovenous haemofiltration in some centres [6].

Our study shows that shunt flows less than 3.0 litre min^{-1} failed to normalize CPG and RPP. Our data show that the relationship between shunt flow index and CI, CPG and RPP behaved in a curvilinear fashion and that an increase in shunt flows led to an increase in RPP and a decrease of CPG linearly when shunt flows were decreased (< 3.5 litre min^{-1}) but optimized CPG (< 5 mm Hg) and RPP (> 60 mm Hg) to only a small extent when shunt flows were great (> 5 litre min^{-1}).

TRACHEAL TUBE CUFF INFLATION AS AN AID TO BLIND NASOTRACHEAL INTUBATION

A. C. VAN ELSTRAETE, J. H. PENNANT, N. M. GAJRAJ AND R. A. VICTORY

SUMMARY

We have assessed the efficacy of tracheal tube cuff inflation in the oropharynx as an aid to blind nasotracheal intubation in 20 ASA I and II patients undergoing elective oral surgery. The trachea was intubated once using the technique of tracheal tube cuff inflation in the oropharynx and once keeping the tracheal tube cuff deflated throughout the manoeuvre. With the cuff deflated, intubation was successful in nine of 20 (45%) patients; in eight of 20 (40%) it was successful on the first attempt. With the tracheal tube cuff inflated, intubation was successful in 19 of 20 patients (95%), 15 of 20 (75%) of these on the first attempt. The success rates were significantly different ($P < 0.01$*). Times to intubate were not significantly different (*$P > 0.05$*). We conclude that, in normal patients, tracheal tube cuff inflation in the oropharynx increases the success rate of blind nasotracheal intubation.* (Br. J. Anaesth. 1993; **70**: 691–693)

KEY WORDS
Intubation: blind nasotracheal.

Blind nasotracheal intubation is a useful technique, although malpositioning results in variable success rates. Several manoeuvres have been described in order to avoid this problem. Inflation of the tracheal tube cuff has been described in a case report as an aid to blind nasotracheal intubation [1], although its efficacy has not been assessed formally. This prospective, randomized study was designed to determine if tracheal tube cuff inflation in the oropharynx improves the success rate of blind nasotracheal intubation in normal, paralysed patients.

METHODS AND RESULTS

After Institutional Review Board approval, informed written consent was obtained from 20 ASA I and II patients scheduled to undergo elective oral surgery requiring nasotracheal intubation. Patients with airway abnormalities such as tracheal deviation were excluded.

After premedication with ranitidine 150 mg and sodium citrate 30 ml orally, and after preoxygenation for 3 min, anaesthesia was induced with thiopentone 5 mg kg^{-1} and fentanyl 2 $\mu g\ kg^{-1}$ i.v. Neuromuscular block was produced with vecuronium 0.1 mg kg^{-1} and monitored using a peripheral nerve stimulator. Additional intraoperative monitoring consisted of electrocardiography, capnography, finger pulse oximetry and non-invasive automated arterial pressure measurement. Arterial pressure was recorded at 1-min intervals.

The patient's lungs were ventilated with 1% isoflurane in oxygen using a face mask until complete muscle paralysis was demonstrated using the nerve stimulator. Patients were positioned supine with the head placed in the "sniffing" position before intubation. A size 7.0- or 8.0-mm polyvinylchloride cuffed tracheal tube was selected according to the patient's weight. The distance from the nostril to the oropharynx was estimated by aligning the tracheal tube against the side of the patient's face before intubation. The tracheal tube was then introduced via the right nostril and advanced until there was a loss of resistance and the tip was positioned in the oropharynx.

The trachea was intubated blindly by a junior resident, once using the technique of cuff inflation and once keeping the cuff deflated throughout the manoeuvre. The order of intubation was determined using a table of random numbers. The times taken to intubate the trachea and the number of attempts and failures were recorded for each procedure.

The tracheal tube cuff was inflated in the oropharynx using 15 ml of air [1] and then advanced gently by the anaesthetist until slight resistance was felt as the inflated cuff made contact with the vocal cords. At that time it was deflated and the tracheal tube advanced into the trachea, whereupon the cuff was reinflated (fig. 1).

The time taken to intubate the trachea was measured from the moment the anaesthetist held the tracheal tube with its tip already positioned in the oropharynx, until correct tracheal placement was confirmed by an end-tidal carbon dioxide partial pressure greater than 3.3 kPa.

After satisfactory insertion of the tracheal tube, the patient's lungs were ventilated manually for 1 min. The tube was then withdrawn to its pharyngeal position and the same anaesthetist intubated the trachea using the second technique.

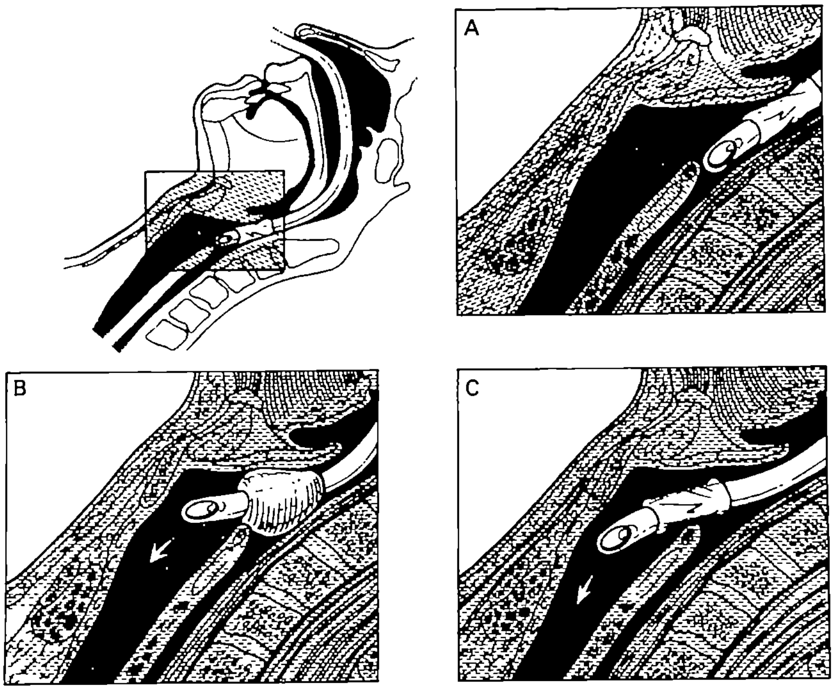

FIG. 1. Technique of tracheal tube (TT) cuff inflation in the oropharynx for blind nasotracheal intubation. A: The tip of the TT is positioned in the oropharynx. B: The cuff is inflated using 15 ml of air and the TT is advanced until the cuff contacts the vocal cords. C: The cuff is deflated and the TT is advanced into the trachea.

A maximum of three attempts was allowed for each intubation. If at any time the arterial oxygen saturation decreased to less than 90% or if cardiovascular variables changed more than 20% from baseline values, the procedure was abandoned, the patient excluded from the study and intubation performed using direct laryngoscopy. If the first procedure failed three times, the second procedure was performed. If the second procedure failed three times, the trachea was intubated using direct laryngoscopy.

Data were expressed as mean (SD) and analysed using the chi-square and paired Student's t tests as appropriate. $P < 0.05$ was considered significant.

Two of the patients were female and 18 male. Their ages ranged from 18 to 60 yr (mean 34 yr), their weights from 57 to 92 kg (mean 72 kg). Intubation was successful in nine of 20 patients (45%) when the tracheal tube cuff was kept deflated throughout, and in 19 of 20 patients (95%) using the technique of tracheal tube cuff inflation in the oropharynx. This difference in success rates was statistically significant ($P < 0.01$). Intubation was unsuccessful in one patient using both techniques. Mean times to intubate were 22.3 (10.9) s with the cuff deflated and 26.2 (15.0) s with the cuff inflated. This difference was not statistically significant ($P > 0.05$). Success on the first attempt at intubation occurred in eight of 20 subjects (40%) with the cuff deflated, but in 15 of 20 subjects (75%) when the tracheal tube cuff was inflated in the oropharynx.

COMMENT

Blind nasotracheal intubation was first described by Magill in spontaneously breathing patients using breath sounds as a guide to placement [2], and still remains a useful technique. In certain circumstances, such as pharyngeal bleeding, it may be preferable to fibreoptic intubation [3].

However, misplacement of the tracheal tube is a problem. It may become positioned in the oesophagus, on the anterior commissure of the larynx, in the vallecula or in the pyriform fossa. Techniques for aiding correct placement other than listening for breath sounds include flexion, extension or rotation of the neck, rotation of the tracheal tube and digital manipulation of the larynx [4]. Also, a fibreoptic bronchoscope may be passed through the tube [5].

We have shown that tracheal tube cuff inflation in the oropharynx is effective in improving the success rate of blind nasotracheal intubation in paralysed patients.

In the presence of normal pharyngeal anatomy, inflation of the tracheal tube cuff in the oropharynx is assumed to centre the tip of the tube and to direct it anteriorly towards the larynx. As a result, misplacement of the tracheal tube into the oesophagus or pyriform fossa may be avoided. Cuff inflation in the oropharynx could theoretically traumatize the upper respiratory tract. We did not perform postoperative laryngoscopy, but believe that cuff inflation would cause less trauma than multiple attempts at intubation. This technique does not require any additional equipment or manipulation of the head or neck and may be useful in cases of cervical spine trauma or immobility. It remains to be established if this technique improves the success rate of blind nasotracheal intubation in cases of difficult intubation. Further controlled studies in this area would be valuable.

POTENCY ESTIMATION OF MIVACURIUM: COMPARISON OF TWO DIFFERENT MODES OF NERVE STIMULATION

V. R. MADDINENI, R. K. MIRAKHUR, R. COOPER AND E. McCOY

SUMMARY

*We have assessed the potency of mivacurium, a new non-depolarizing neuromuscular blocker, using two different modes of nerve stimulation in patients anaesthetized with thiopentone, fentanyl and nitrous oxide in oxygen. The force of contraction of adductor pollicis was measured after single twitch stimulation at 0.1 Hz or train-of-four stimulation (TOF) at 2 Hz every 10 s. Dose–response curves were constructed using a single-dose method for each mode of stimulation. The ED_{50} and ED_{95} were 43 μg kg^{-1} and 83 μg kg^{-1}, respectively, for the single twitch responses and 34 μg kg^{-1} and 66 μg kg^{-1}, respectively, for the first response of the TOF stimulation. The difference between the ED_{95} doses was not significant (*P *= 0.051), but the difference between the ED_{50} doses was significant (*P *= 0.03), suggesting greater sensitivity of the neuromuscular junction using TOF stimulation. The results show that the information obtained using single twitch stimulation at 0.1 Hz is not the same as that obtained from the first response of the TOF stimulation.* (Br. J. Anaesth. 1993; **70**: 694–695)

KEY WORDS

Neuromuscular relaxants: mivacurium. Monitoring: single twitch, train-of-four.

Mivacurium chloride is a recently-developed non-depolarizing neuromuscular blocking drug with a relatively short duration of action because of its breakdown by plasma cholinesterase [1].

Previous studies with other neuromuscular blockers have shown that the mode of stimulation influences their estimated potency, the train-of-four (TOF) mode of stimulation at 2 Hz being associated with smaller ED_{95} values compared with single twitch stimulation at 0.1 or 0.15 Hz [2, 3]. In the present study, we have estimated the potency of mivacurium using two different modes of nerve stimulation.

METHODS AND RESULTS

We studied 60 ASA I or II patients aged 18–65 yr with their written informed consent and approval from the Regional Medical Ethics Committee. They were anaesthetized with thiopentone 3–5 mg kg^{-1}, fentanyl 1–3 μg kg^{-1} and nitrous oxide in oxygen and further increments of fentanyl, thiopentone, or both, as required. Ventilation of the lungs was assisted to maintain an end-tidal carbon dioxide concentration at 4.5–5.0%.

The ulnar nerve was stimulated percutaneously at the wrist using supramaximal stimuli of 0.2 ms duration and the resultant force of contraction of the adductor pollicis muscle recorded using a force displacement transducer and a neuromuscular function analyser (Myograph 2000, Biometer Ltd). After stabilization of the control responses, six patients each were allocated randomly to receive mivacurium 20, 40, 60, 80 or 100 μg kg^{-1} and to be stimulated in a single twitch mode at 0.1 Hz or in a TOF mode at

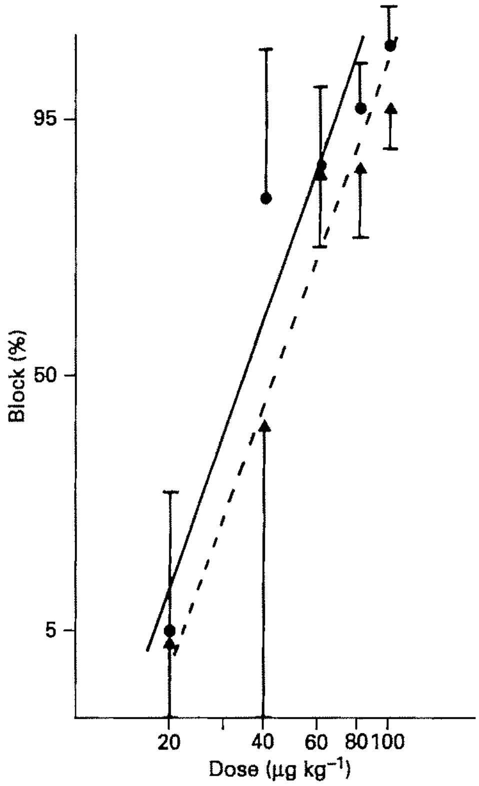

FIG. 1. Dose–response curves for mivacurium using the single twitch (▲--▲) and the train-of-four modes of stimulation (●—●). Individual points represent mean (SD).

MCCOY, F.F.A.R.C.S.I.; Department of Anaesthetics, The Queen's University of Belfast, Whitla Medical Building, 97 Lisburn Road, Belfast BT9 7BL. Accepted for Publication: December 21, 1992.
Correspondence to R.K.M.

2 Hz every 10 s and the maximum depression of twitch height (single twitch) or of the first response in the TOF (T1) was then recorded. We used a single dose technique as described previously for neuromuscular blockers with relatively short duration of action [4].

The twitch height data were subjected to arc-sine transformation as described previously [4] for responses involving the extreme points (0 and 100 %) on the dose–response curves. Regression analysis of the data was performed, dose–response curves constructed for each mode of stimulation and the values of ED_{50} and ED_{95} estimated. These were tested for statistical significance ($P < 0.05$) using Student's *t* test.

The patients in each of the five groups within each mode of stimulation were comparable in age, weight and height. The degree of block attained increased in a dose-related manner, varying from 4 % and 5 % with the single twitch and TOF modes, respectively, after mivacurium 20 $\mu g\ kg^{-1}$, to 97 % and 99 %, respectively, after mivacurium 100 $\mu g\ kg^{-1}$.

The dose–response curves (fig. 1) showed that the TOF mode of stimulation was associated with a greater degree of block. However, there was no significant difference between the slopes. The calculated values of both the ED_{50} and the ED_{95} were smaller with the TOF mode of stimulation. The ED_{50} values of 43 $\mu g\ kg^{-1}$ and 34 $\mu g\ kg^{-1}$ with single twitch and TOF modes of stimulation, respectively, differed significantly ($P = 0.03$). ED_{95} values were 83 $\mu g\ kg^{-1}$ and 66 $\mu g\ kg^{-1}$ with the single twitch and TOF modes of stimulation, respectively. The differences between the groups with the ED_{95} dose, however, failed to attain statistical significance ($P = 0.051$).

COMMENT

We have shown that the mode of stimulation affected the dose–response curve and apparent potency of mivacurium chloride; TOF stimulation produced apparently greater potency. ED_{50} values were significantly different ($P = 0.03$), whereas ED_{95} values just failed to attain statistical significance ($P = 0.051$). This may reflect relatively large individual variability among the patients in response to neuromuscular blocking drugs. In these respects, mivacurium behaves similarly to atracurium and rocuronium [2, 3]. The estimates of potency in the present study are similar to those described by others who used comparable modes of stimulation.

The apparently greater sensitivity using TOF stimulation may result from increased muscle blood flow, as has been suggested for the earlier onset of neuromuscular block using this mode of stimulation [5]. It may be possible also that the more rapid rates of stimulation used in the TOF mode induced muscle fatigue and diminished the responsiveness of the stimulated muscle in the presence of a neuromuscular blocking agent, as the stimulus frequency has been shown to reduce both the dose of blocking drug required and the time for onset of a given degree of neuromuscular block [6]. The present study supports the contention that it is important and relevant to state the method of stimulation used when comparing potencies of different myoneural blockers [2]. From a clinical point of view, it is probably preferable to use the dose (or multiples of it) estimated using the single twitch mode, as it is a more reliable index of neuromuscular block for procedures such as tracheal intubation [6].

ACKNOWLEDGEMENT

Supplies of mivacurium and financial assistance were received from the Wellcome Foundation.

CASE REPORT

A BIFURCATED ENDOBRONCHIAL TUBE IN THE MANAGEMENT OF LARYNGOTRACHEO-OESOPHAGEAL CLEFT REPAIR

R. AHMAD, K. A. SAMI AND A. RABEEAH

SUMMARY

We describe the management of laryngotracheo-oesophageal cleft Type III using a bifurcated endobronchial tube. When the cleft was opened for repair, we were able to obtain effective control of the airway, which is the main problem in this rare congenital anomaly. Commercial tubes are not available, so we made the tube on the day of surgery, immediately before operation. (Br. J. Anaesth. 1993; **70**: 696–698)

KEY WORDS
Equipment: endobronchial tube. Anaesthesia: paediatric. Surgery: laryngotracheo-oesophageal fistula.

Laryngotracheo-oesophageal cleft (LTEC) is a rare congenital anomaly with a high mortality rate resulting from delay in diagnosis and chronic aspiration [1]. More than 170 cases have been reported in the literature [2]. In a classification devised by Pettersen [3], Type I LTEC involves the larynx, Type II extends to the 6th tracheal ring, (corresponding to the cervical trachea) and Type III lesions extend to the carina. Type IV lesions have been described recently and may extend into one or both mainstem bronchi [4]. The anaesthesia literature contains few references to anaesthetic management of these patients, but describes the incidence, symptomatology and embryology of LTEC [5], anaesthesia for endoscopic procedures in Type I lesions [6], difficult intubation in a neonate with associated tracheal stenosis [7] and one patient with a staged repair of an extensive cleft [8]. We have recently used a bifurcated endobronchial tube as suggested in the surgical literature [9], for a combined cervical and thoracic approach for the repair of a Type III cleft in a neonate.

CASE REPORT

A 1-month-old baby girl was admitted to our Hospital with a referral diagnosis of tracheo-oesophageal fistula. She was born in a district hospital and developed respiratory distress after oral feeding.

On admission, the baby was found to be cyanotic, despite receiving 100 % oxygen. Chest x-ray showed bilateral infiltrates and areas of atelectasis more pronounced in the right chest. Oesophageal contrast studies revealed the presence of a laryngotracheo-oesophageal cleft down to the carina. Other congenital anomalies were not found. A nasogastric tube was passed, with some difficulty, to decompress the stomach and i.v. fluids were given. The patient was brought to the operating theatre for endoscopic examination. Her trachea was intubated, while she was awake, with a 3.5-mm tracheal tube and spontaneous ventilation maintained with halothane and oxygen to avoid acute dilatation of the stomach, aspiration and inadvertent intubation of a tracheo-oesophageal fistula—the diagnosis with which the patient was referred. Laryngotracheobronchoscopy followed by oesophagoscopy confirmed the diagnosis of LTEC Type III. A central venous catheter was inserted for parenteral nutrition and the patient was transferred to the Paediatric Intensive Care Unit with the tracheal tube in place. CPAP was instituted.

After 2 weeks of parenteral nutrition and treatment for pneumonia, the patient returned to the operating theatre for total repair of the LTEC by a combined cervical and thoracic approach. It was considered essential to isolate the lungs so that ventilation could be controlled without danger of aspiration of gastric secretions or blood from the surgical procedure. A bifurcated endobronchial tube was constructed [9] as follows. The bevel of a 3.5-mm tracheal tube was cut off and the end of the tube split for 1 cm in the coronal plane. The distal 2.5-cm ends of two, 3.0-mm tracheal tubes were cut off and slid over the split ends of the 3.5-mm tracheal tube with the bevels facing laterally. This combination was stitched together at each joint with a No. 3-0 silk suture through the walls, but not the lumen, of the tubes. The endobronchial limbs were then cut along their lateral surfaces to permit ventilation of the upper lobes, and the endobronchial ends brought together by a slip-knot of No. 2 silk suture to facilitate passage of the bevelled ends through the glottis.

Anaesthesia was induced with halothane in oxygen through the existing, standard tracheal tube which

Correspondence to R.A.

was then removed and the endobronchial tube passed gently through the vocal cords with the distal ends of the tube in an antero-posterior alignment. After passage through the cords, the tube was turned 90 ° and advanced until resistance was met. Auscultation of the lungs revealed good bilateral breath sounds and a chest x-ray showed the distal ends of the tube positioned at the carina. Assisted hand ventilation revealed no major air leak through the cleft and neuromuscular block was produced with atracurium. Radial arterial and central venous catheters were inserted. The patient was placed in the left lateral position and a right thoracotomy performed through the 3rd intercostal space. The LTEC was identified and dissected free. When the cleft was opened, the surgeon advanced the two wings of the endobronchial tube into the mainstem bronchi under direct vision. The cleft did not have sufficient tissue for reconstruction of both trachea and oesophagus. The distal oesophagus was dissected from the cleft and suture-ligated 3 cm proximal to the gastro-oesophageal junction. The trachea was repaired using the posterior oesophageal wall. The chest was closed and the proximal LTEC was repaired through a left cervical approach. A cervical oesophagostomy was created and a gastrostomy feeding tube was inserted.

Vital signs and oxygenation remained satisfactory throughout the procedure. The smallest oxygen saturation recorded by pulse oximetry was in the range 86–89 %. $P\text{CO}_2$ was 5–6 kPa. The patient was transferred to the Paediatric ICU with the endobronchial tube still in position and the lungs ventilated artificially. A suction catheter could be passed easily through the endobronchial tubes to each lung.

After 1 week of mechanical ventilation, the tracheal tube was found to have slipped back from its endobronchial position into the trachea and it was decided to replace the double-lumen tube with a conventional tracheal tube. During the process of extubation, one of the endobronchial wings became detached and remained in the trachea. The tube was removed easily with the help of a paediatric bronchoscope. The trachea was then reintubated with a 4.0-mm tracheal tube. Two weeks after repair, the trachea was extubated, but the patient soon developed respiratory distress. Bronchoscopy under general anaesthesia revealed tracheomalacia and tracheotomy was performed using a Shiley tracheostomy tube.

Six months after the surgery, the infant was brought back to the operating theatre, gastric tube interposition was used to replace the oesophageal gap, and the cervical oesophagostomy was closed.

DISCUSSION

Successful initial management of patients with Type III LTEC is based on early diagnosis, with precise definition of the extent of the cleft determined at endoscopy, establishment of a secure airway to provide protection against aspiration and adequate nutrition [4]. Early diagnosis requires a high index of suspicion, accurate interpretation of a barium oesophogram and thorough endoscopic evaluation [2]. Symptoms in the neonate range from inspiratory stridor, hoarse cry, cyanosis and feeding difficulties, to massive aspiration seen in Types III and IV [1, 2]. Diagnosis may often be delayed and there are case reports describing previous endoscopies [5], laryngoscopies by experienced anaesthetists [1] and even surgical repairs of tracheo-oesophageal fistula in which the presence of LTEC was not recognized [1, 2]. It is recommended that all infants thought to have tracheo-oesophageal fistula should undergo thorough endoscopy, as 6 % of tracheo-oesophageal fistula patients are found to have LTEC [1]. Endoscopic manoeuvres which increase the visibility of LTEC include placement of tracheal tube to stent the cleft open or pressure on the posterior larynx [5, 9]. Radiological examination with barium may fail to distinguish between communication and aspiration but, in experienced hands, opacification of the bronchial tree may be produced with less than 1 ml of contrast [9]. Early treatment of LTEC is essential to prevent the development of chronic lung disease [4].

Perioperative airway protection against aspiration in Type II clefts may be provided by placement of a conventional tracheal tube or tracheostomy below the inferior border of the cleft. Posterior migration of these breathing tubes into the oesophagus occurs with a more extensive LTEC, with potentially serious consequences [11]. High gastric division with gastrotomy drainage from the upper portion (to reduce the chances of aspiration) and gastrotomy feeding to the lower portion (for nutritional support) have been used in the perioperative management of LTEC patients [11]. Recent surgical literature, however, recommends a one-stage repair of LTEC with fundoplication [1].

In our opinion, anaesthesia for endoscopic evaluation of these patients should be managed with spontaneous ventilation and inhalation agents combined with topical anaesthesia of the upper airway [6, 7]. This technique reduces the potential for gastric distension and aspiration. Some Type I LTEC may be closed surgically at endoscopy [1]. Surgical repair of Type II clefts may be accomplished by one of several surgical approaches through the neck and requires anaesthesia via a tracheal tube or a tracheostomy, with care taken to ensure that the tip of the tube cannot slip into the oesophagus during surgical manipulation. With more extensive clefts, however, the airway must be secured by other methods. In one approach, for a cleft which was described as extending to the carina, a Foley catheter was passed into the stomach, the balloon inflated and subsequent traction applied [8]. The patient was then anaesthetized and the trachea intubated orally for a gastric division procedure. Two months later, the cleft was repaired through the neck and a tourniquet was placed around the distal trachea and oesophagus to prevent anaesthesia gas leakage or aspiration of blood and secretions. This technique was not considered suitable for a combined cervical and thoracic operation. It may be possible also to manage the airway during an extensive cleft repair with endobronchial intubation and one-lung anaesthesia using a conventional tracheal tube [10], although when the standard tube is withdrawn into the trachea at the completion of the repair, the tracheal suture line may be jeopardized by motion of the tube and during suctioning.

We chose to use the technique described by Donahoe and Gee [9]. We were unable to obtain the manufactured tube they described, but were able to fashion a similar "home made" version. This assembly allowed us complete control of the airway during thoracotomy and in the postoperative period. The movement of the endobronchial tube back into the trachea on the 8th day after operation was unfortunate, as we had planned to leave it for 2 weeks to give some time for healing to occur. The subsequent separation of the endobronchial wing was an unexpected and potentially dangerous complication. As a bifurcated tube is no longer commercially available as a special order product, cyclohexanone (Fisher Scientific catalogue), a PVC cement, can be used safely to make a stronger bond between the component parts [D. Flynn, Mallinckrodt Corp., personal communication].

Postoperative complications of LTEC repair include anastomotic leak, recurrence of the cleft or tracheo-oesophageal fistula, recurrent laryngeal nerve injury and persistent aspiration [1, 2]. After operation, the tracheal tube should remain *in situ* for several weeks until the suture lines have healed [4]. Long term tracheostomy is often needed because of tracheomalacia [4]. Fundoplication is advised to avoid the chronic aspiration which results from the long-term abnormality of swallowing function in patients with extensive LTEC despite restoration of the anatomical integrity of the trachea and oesophagus [1, 11].

CORRESPONDENCE

HAEMOSTASIS AND THROMBELASTOGRAPHY: A CAUTIOUS NOTE

Sir,—We read with interest the recent review article entitled "Thrombelastography" by Mallett and Cox [1]. In the article, the authors attempted to examine the growing controversy on the clinical use of thrombelastography (TEG) in cardiac surgery and other operative procedures. The review article reflected that TEG may predict postoperative blood loss [2], yet failed to discuss the observations made by Wang and colleagues [3] and Horkay and colleagues [4] which identified no predictive power of an abnormal TEG profile for excessive postoperative haemorrhage in adult cardiothoracic surgical patients. Paradoxically, both groups identified TEG evidence of a hypercoagulable state in several patients after surgery (Wang and colleagues 13%, Horkay and colleagues 60%)—findings inconsistent with previously reported haemorrhage-induced TEG derangements. However, in contrast, in other studies performed in this unit, in a cohort of paediatric patients undergoing open heart surgery, TEG predicted with 100% accuracy (specificity 73%) those patients who developed excessive bleeding [5]. This was reflected by a TEG *hypocoagulable state* (diminished maximum amplitude (MA) phase $P < 0.01$, prolonged clot formation time (K phase) $P < 0.05$). The reviewers also cited the work of Tuman and colleagues [6], who reported that massive blood loss was associated with a trend towards increased coagulability (where losses were replaced only with crystalloid and packed red blood cells) which is at variance with the premise of the proposed potential of TEG to predict bleeding.

Furthermore, Mallett and Cox suggested that TEG may be a useful means of assessing *in vitro* platelet function in whole blood, citing an abstract which identified correlations of the MA phase of TEG with platelet count and also with aggregation responses to collagen and ADP [6]. However, at variance with this finding, later in the review they cited data from several groups [7–9] demonstrating the inability of TEG to delineate platelet dysfunction in the presence of small doses of aspirin, a known inhibitor of platelet aggregation. They explain this observation by reference to the inability of aspirin to inhibit thrombin-stimulated aggregation. Yet one would expect thrombin to have been present similarly as a confounding factor in the study identifying the aggregation correlates of TEG [6].

In conclusion, we recommend that caution be exercised when interpreting TEG in different patient populations (e.g. adults and paediatric) and settings when treating haemostatic derangements. Prospective longitudinal studies are required to assess the accuracy and specificity of TEG prediction of operative bleeding and more powerful interventional studies are required to determine if TEG-guided blood product administration can reduce transfusion requirements or blood loss.

Sir,—Thank you for the opportunity to reply to the letter by Gupta and associates.

The recent papers to which they refer [1, 2] were published after our review was submitted and therefore could not be considered at that time.

These papers appear to contradict previously published studies on this subject [3–5] in that they were unable to demonstrate that thrombelastography (TEG) can reliably predict postoperative bleeding in cardiac surgical patients. However, differences in these studies should be interpreted with care. Whether the patient populations are strictly comparable is debatable, given the extremely high prevalence of fibrinolysis and hypocoagulation before operation [1]. Also, where there is an unusually high prevalence of preoperative coagulopathies it is important to correlate TEG abnormalities with other coagulation tests in order to differentiate adequately real coagulation problems from any artefact of the tracings which could introduce methodological flaws and problems with interpretation of the data. It is difficult also to make direct comparisons when there are obvious differences in the design and construction of these studies.

Postoperative haemorrhage is related to many interrelated factors, including the quality of surgical haemostasis, the nature of the haemostatic defects, patient temperature, neuroendocrine responses and drug therapy; comparisons of results must take these factors into consideration. An abnormal TEG *per se* does not necessarily imply that particular patients may bleed excessively; however, if they do, it offers some objective variables on which to base corrective therapy. It is also of note that *all* reported series, including those of Wang and colleagues [1] and Horkay and colleagues [2], confirm the specificity of the TEG in detecting surgical bleeding in cardiac surgical patients.

The study by Tuman and colleagues [6], on the effects of progressive (normovolaemic) surgical blood loss on the TEG, demonstrated that *normal* individuals have a "coagulation reserve" and can have adequate haemostatic function despite dilution of their clotting factors and platelet numbers. This is compatible with the fact that a 20% factor value is sufficient to maintain haemostasis. It is only when dilution becomes excessive (> 80% of estimated blood volume) that a proportion of patients develop clinical and TEG evidence of hypocoagulability. This illustrates how important it is that treatment is given on an individual basis, rather than according to a generalized format, and that coagulation is monitored serially during major procedures.

Postoperative hypercoagulability is well known to occur as part of the stress response to surgery and trauma, and is a particularly common finding in patients with cardiovascular disease [7]. It is not surprising, therefore, that both Wang's and Horkay's groups [1, 2] found a significant incidence after surgery. Identification by the TEG of a hypercoagulable state is of obvious clinical importance because of the association with a high incidence of postoperative thrombotic events [8].

All published studies to date show that low-dose aspirin does not alter the TEG and therefore it cannot be used to identify those patients at increased risk of bleeding. The mechanisms by which aspirin acts *in vivo* to protect against thrombotic complications are still incompletely understood. Aspirin irreversibly inactivates cyclo-oxygenase and blocks the arachidonic acid pathway to the platelet release reaction [9]. ADP and collagen are potent agonists that stimulate platelet aggregation *independently* of the arachidonic acid pathway [10] and therefore the MA is not affected by aspirin. The TEG is unable to measure the initial phase of platelet adhesion which requires interaction with the vascular endothelium. The TEG monitors the thrombin generation of a blood sample. Aspirin does not significantly affect thrombin generation, therefore the structural function of platelets in a thrombin-induced clot is still measurable in the TEG and any aspirin effects may not be observable for the onset of clotting. Measurement of the bleeding time still remains the most reliable simple test of aspirin effect on platelet function [11].

The successful implementation of TEG as a tool for monitoring coagulation requires care and experience in performing the test and also in interpreting its results. Despite its limitations, it helps to improve the assessment of coagulation status during operation. It would seem logical that a method of monitoring coagulation that allows serial measurement of whole blood clot formation and stability is of more clinical relevance to a patient undergoing surgery than a limited series of tests that are performed on citrated plasma and look only at the early stages of clot formation. As with any form of monitoring, decisions regarding therapeutic intervention should always be based on *clinical* grounds in addition to the results of tests.

CONTINUOUS SUBARACHNOID INFUSION OF 0.125% BUPIVACAINE FOR ANALGESIA DURING LABOUR

Sir,—The findings of McHale and colleagues [1] raise several points for discussion. The authors claim that the subarachnoid administration of dilute solutions of bupivacaine produces effective analgesia in labour. However, on further examination there appear to be few advantages of this technique compared with extradural infusions. Moreover, the disadvantages associated with this method should not be overlooked.

This method of analgesia is associated with a high degree of motor block which may have accounted for the increased rate of instrumental delivery, as relaxation of the muscles of the pelvic floor may lead to malrotation of the fetal presenting part [2]. The aetiology of long-term backache after childbirth has been linked with motor block during labour [3]. Those authors stated that "the mother was allowed to adopt any position she found comfortable." Labouring women and their attending midwives must be taught the correct position to be adopt after the administration of regional analgesia: mothers must ensure that the back is kept straight, minimizing stressful postures and therefore reducing long-term backache. Maternal satisfaction has been demonstrated to be greater when motor block has been minimized by the use of spinal opioids [4]; although mothers in McHale and colleagues' study considered that analgesia had been excellent or good when questioned following delivery, there was no such control group with which a comparison could be made.

Long-term neurological damage after subarachnoid infusions [5] was not discussed in the paper by McHale and colleagues. Although this complication has been reported only after the use of stronger concentrations of local anaesthetics, the seriousness of this problem warrants its inclusion.

Motor block was said, by the authors, to be undertaken on the basis of the Bromage motor scale. However, the scale described bears little resemblance to Bromage's original scale [6] and although many subsequent authors have modified this scale [7], the method used by McHale and colleagues lacked accuracy, as it assessed the whole leg rather than the hip, knee and ankle joints as intended by Bromage.

The authors suggest that one of the benefits of their technique would be rapid extension of the block in the event of an operative or instrumental delivery. They describe how, with 0.5% heavy bupivacaine 1–2 ml, the upper limit of the block produced a sensory loss to T4 in less than 13 min. A recent study by Price and colleagues [8] demonstrated that extradural block could be extended for Caesarean section with 2% lignocaine in less time than this.

The quality of analgesia produced by the subarachnoid infusions is described by the authors as effective. However, when one considers that the mean duration of labour was 3 h 13 min and the average number of top-ups was 2.8, it appears that this method is far from effective. With an infusion technique, even using local anaesthetics as the sole agent, this number of top-ups is unacceptably large. A review by Gaylard [9] cited many extradural infusion procedures in which the number of top-ups required was much smaller.

With the very high instrumental delivery rate reported, the authors comment that "this may be a reflection of the effectiveness of the analgesia in the second stage." The maintenance of infusion analgesia throughout the second stage has been demonstrated by Chestnut and colleagues [10] not to increase the number of instrumental deliveries. We have achieved a 60% spontaneous delivery rate in our extradural population using an infusion of 0.08% bupivacaine containing sufentanil $2\ \mu g\ ml^{-1}$. Infusions were continued into the second stage and nearly all women reported minimal or no discomfort at delivery [11].

Overall, the technique described in the paper has little to commend it, and many potential disadvantages such as excessive motor block, a high incidence of instrumental and operative deliveries, inadequate maintenance of analgesia and the potential for neurological sequelae.

Sir,—Thank you for the opportunity to reply to Dr Russell's comments. We did not advocate the use of continuous subarachnoid infusions of local anaesthetic for analgesia instead of extradurals, but merely reported our findings when using a technique which had not been used before during labour.

The implication that the instrumental delivery rate in our group of primiparae (40%) receiving regional analgesia during labour is exceptionally high is unfounded. Others have reported rates greater than 40% [1–3]. Kaminski, Stafl and Aiman compared a group of primiparae receiving extradural analgesia with a control group. The frequency of instrumental delivery was 52% in the extradural group, compared with 23% in the controls [4]. The rotational forceps rate of 15% in our study is similarly unexceptional, as other groups have reported midcavity forceps delivery rates of 12% in primiparae receiving extradural analgesia [4]. This suggests that pelvic muscle relaxation after intrathecal infusions did not lead to malrotation of the fetal presenting part.

The aetiology of long-term backache after labour is not yet known, and as yet there are no prospective studies linking the degree of motor block to the incidence of long-term backache [5].

Our assessment of motor block was indeed on a four-point scale as described by Bromage [6]. Full flexion of both knees and feet implied absence of motor block; that the mother was just able to move her knees indicated partial motor block; no knee movement but still foot movement implied almost complete block; inability of the mother to move either feet or knees indicated complete motor block.

Only four women required extension of the subarachnoid block for Caesarean section. Although one block took 13 min to reach T4, the other blocks were established in 5, 6 and 10 min. Whereas the appropriate drug and volume for an extradural top-up are known, we were naturally cautious when we administered bupivacaine into the subarachnoid space. As experience with this technique increases it will become more refined and, similarly, as different infusion rates are used throughout labour the number of top-ups required to maintain analgesia will decrease.

All new techniques are associated with a learning curve. The advantages of a rapid onset of good analgesia, with the potential for manipulation of the solution injected and ease of extension of the block in the case of an operative or instrumental delivery, suggest that there may be a place for subarachnoid infusions during labour. However, further use of the technique will be limited as a result of the cases of cauda equina syndrome in America. These have led to the Food and Drug Administration recalling all licences for intrathecal use of microcatheters. In these cases the drugs involved were 5% lignocaine with 7.5% glucose (three cases) and 1% amethocaine with 10% glucose (one case). The aetiology of the neural damage has been postulated to result from a combination of maldistribution and a relatively large dose of local anaesthetic around the nerve roots [7].

PREOPERATIVE DRINKING AND GASTRIC CONTENTS

Sir,—We share Professor Strunin's puzzlement [1] that there is an implication of something revolutionary in the paper of Drs Phillips, Hutchinson and Davidson [2] on preoperative fasting. In July of 1991, we published a paper [3] which investigated virtually the same regimen and drew exactly the same conclusion. Of particular note is the similarity of the confidence intervals of the difference in the residual gastric volumes of the two groups in each paper. This was present despite smaller sized study groups.

Among the minor differences between this new study and ours are the following: we allowed only water whereas they allowed "clear fluids"; they used a double-lumen tube to empty the stomach: we used a single-lumen tube and rolled the patient during aspiration; *all* our patients were premedicated with temazepam; the mean gastric pH of both our groups were less than 2.5 (in both studies the confidence intervals of differences in gastric pH are wide).

Sir,—In his Editorial on fasting before surgery [1], Professor Strunin questions why none of Mendelson's patients [2] died after inhaling liquid acid gastric contents, yet aspiration is a significant cause of maternal mortality today. We wish to offer an explanation. As stated in Mendelson's paper, a mixture of nitrous oxide, oxygen and ether was used in all cases. As late as 1959, junior anaesthetists in one London teaching hospital were forbidden to use any other technique for all forceps deliveries. Despite atropine 0.6 mg, maternal salivation was invariably profuse. Coughing, swallowing, retching and vomiting were considered normal events at induction. Partial alkalinization of gastric contents by saliva, in-addition to a diluent and "lining" effect of copious tracheobronchial secretions, might have made aspiration a survivable insult. The contemporary practice of i.v. agent and suxamethonium in rapid sequence does not afford the lungs this potential protection.

Sir,—I agree with Professor Strunin [1] that it is time for new guidelines on preoperative starvation. I wish to raise one issue and make one comment.

First, in the United States several children are admitted just before surgery and may recently have been or still be, chewing bubble gum! There are several approaches amongst anaesthesia staff: some ignore the chewing of gum and accept the children as starved; others take the view that chewing gum increases gastric secretion via conditioned and unconditioned reflexes, such as sight, smell and taste, leading to increased gastric volume, at low pH, which requires a 6-h postponement [2]; yet others believe that chewing gum is equivalent to a clear liquid challenge and should be cleared from the stomach within a 3-h postponement; a fourth group argue that the child who drank recent clear fluids will have diluted his gastric contents and will thus be at less risk than the child who has only chewed gum. This last group would recommend offering a clear liquid drink and postponing for 3 h. Until recently, I followed the first option, but I am now considering adopting the last approach. A small postponement would be less disruptive to the theatre list, but may also discourage the child from chewing gum before any subsequent surgery.

Second, in healthy patients presenting for elective surgery it is perfectly acceptable to allow a 6-h starvation period for solid foods and 3 h for clear liquids. However, despite this apparent simplicity, I have still found patient, nurse and surgical confusion in trying to implement such instructions. The "double time limits" adds to errors, and to the number of rules broken. There have also been several episodes of misunderstanding associated with the term "clear" liquid. Patients have interpreted this to mean "pure", and have allowed themselves assortments of puréed fruit, such as apple. This concept must be made clear to patients or perhaps, as a compromise, patients might only be allowed to drink once in hospital and under nursing vigilance.

If in doubt, a conservative approach is the safest.

2. Kradel B, Hackett A, Johnstone R. NPO includes chewing gum. *Anesthesia and Analgesia* 1992; 74: 621.

Sir,—Drs Read and Vaughan gently chide me for having missed their paper [1] in my editorial [2]. It is, however, nice to see that their results regarding preoperative fasting in Wales are similar to those observed in England and North America. This statement should not be construed as facetious or unkind. Among the many objections that the Medical Ethics sub-Committee of the University of Calgary raised to the procedures of the Canadian studies referenced in my editorial [2] was their belief that results obtained in other countries relating to gastric emptying [3] could not be assumed to be the same as may be obtained in Canada. Studies such as those of Read and Vaughan have proved the Ethics Committee wrong. One criticism that can be levelled at Drs Read and Vaughan is that, having shown that allowing preoperative patients unlimited oral water until 2 h before anaesthesia was not hazardous, they made no recommendations with regard to changing current practice. Others have taken this step and have drawn up guidelines with regard to what is meant by "clear fluids" [4–6] and have not found that patients have difficulties in distinguishing between solids and liquids. It seems that water, carbonated drinks, non-particulate fruit juices and modest quantities of milk or sugar in tea or coffee are all acceptable within the definition of "clear fluids".

The description of ether anaesthesia by Drs Levy and Tunstall may be relevant in relationship to Mendelson's observation [7] that none of his patients died after fluid aspiration. However, ether anaesthesia need not be quite so unpleasant and yet may be safe for obstetrics even by open drop [8]. I still hold the view [graphically described in the *Report on Confidential Enquiries Into Maternal Deaths in England and Wales*, 1976–1978, pp. 80–81] that, although pulmonary aspiration of gastric contents may be the starting point for a potential maternal death, it is other factors such as repeated attempts at tracheal intubation accompanied by intermittent positive pressure ventilation without a secure airway and the resultant hypoxia, inadequate equipment and inexperienced personnel that combine to make death a certainty.

With regard to children, or adults for that matter, chewing gum, I know of no study which equates this with eating and therefore these patients may be managed in the same way as any other starved individual. However, as the letter [9] by Kradel, Hackett and Johnstone describes suctioning gum from the stomach after tracheal intubation, there may be some hazard if patients are anaesthetized still chewing their gum. Therefore, bearing in mind the old Lonnie Donegan song "*Does your chewing gum lose its flavour on the bedpost over-night?*", perhaps the preoperative check list should include making sure that patients have deposited their gum in an environmentally friendly place before induction of anaesthesia.

Sir,—Thank you for the opportunity to respond to Drs Read and Vaughan. As they (and the Editorial accompanying our article) have pointed out, there is nothing revolutionary about suggesting that the period of fluid fasting before surgery should be reduced.

What is surprising is that the majority of anaesthetists still expect and teach that a 4–6 h fast is necessary before elective surgery. In practice, this period is often much longer; in our study the mean fasting time exceeded 12 h [1]. Indeed, the increasing body of research into this subject continues to find that the current guidelines are excessive [2–4].

Sceptics should gain reassurance from the fact that, despite variations in study design, including those noted by Drs Read and Vaughan, similar conclusions have been reached in all these reports. This is most unlikely to be a result of chance or flawed study design.

Our study merely brings to the attention of the profession a long-accepted practice which adds significant discomfort for the majority of elective surgical patients in return for no increase in safety.

EXTRADURAL ABSCESS IN THE POSTPARTUM PERIOD

Sir,—We read with interest the case report by Dr Ngan Kee and colleagues [1] who described a patient in whom an extradural abscess developed after insertion of an extradural catheter for postoperative pain relief after Caesarean section. We report a case of an extradural an extradural abscess which developed spontaneously in a postpartum patient.

A 31-yr-old woman was referred to the regional neurosurgical unit with a 4-day history of severe mid-thoracic back pain, difficulty in micturition, and spastic leg weakness. Eight weeks previously she had been delivered of her fourth child. She did not receive extradural analgesia, and there were no untoward obstetric events. On examination she had marked loss of power in both legs and was unable to stand. Lower limb reflexes were pathologically brisk with upgoing plantars. She had loss of sensation to light touch below T10. Myelography confirmed the presence of a blocked flow of contrast at T8–9. She underwent urgent thoracic laminectomy and drainage of an abscess at T8–9. The fluid aspirated subsequently grew *Staphylococcus aureus* sensitive to benzylpenicillin. Further investigations after operation (including abdominal and pelvic ultrasound) revealed no obvious source for the infection. Six weeks after surgery, neurological deficit was limited to leg weakness on exertion.

This case demonstrates that, although an extradural catheter may provide a nidus for the formation of an extradural abscess, a causal relationship cannot necessarily be assumed. The reported incidence of this complication after lumbar extradural analgesia in obstetrics is less than the rate of spontaneous spinal extradural abscess in the general hospital population. Dr Ngan Kee and colleagues point out that the incidence of spontaneous spinal extradural abscess is 0.2–1.2 per 10000 hospital admissions. The case report of Dr Ngan Kee and colleagues is only the second reported case associated with lumbar extradural catheterization in labour, and they quoted an incidence of 1 in 505000 obstetric extradural blocks, from a previous study [2]. Extradural abscess can develop spontaneously in the postpartum period, and similar neurological problems can occur after general anaesthesia [3].

3. Schreiner EJ, Lipson SF, Bromage PR, Camporesi EM. Neurological complications following general anaesthesia. Three cases of major paralysis. *Anaesthesia* 1983; **38**: 226–229.

Sir,—We read with interest the article by Ngan Kee and colleagues describing a rare complication of extradural anaesthesia, resulting in the patient making a complete recovery after back surgery to release the abscess [1]. *Staphylococcus aureus* was probably a skin contaminant in the case presented, with the bacteria seeding the extradural space by colonizing either down or around the catheter.

Aseptic technique is essential to prevent wound and catheter contamination with skin bacteria. In surgery, 1% iodine has been used as a skin disinfectant for many years and traditionally involves a 10-min scrub. Alexander, Aeri and Plettner described a 1-min preparation with 70% alcohol or 2% iodine in 90% alcohol that produced a reduction in bacterial skin flora similar to that obtained with the 10-min povidone-iodine (1% free iodine) skin preparation [2]. Multidose povidone-iodine bottles have been shown to grow a variety of organisms [3]. At the 1992 Society of Obstetric Anesthesia and Perinatology meeting, Birnbach and colleagues presented the results of a study in which cultures were obtained from povidone-iodine bottles from the labour suite. Bacterial swabs from the cap and solutions revealed *Staphylococcus haemolyticus* and *S. epidermidis*, which were in greater quantities in previously opened bottles compared with newly opened bottles.

In preparing the skin for extradural anaesthesia, we recommend that sterile povidone-iodine swabs should be used in a spiral motion with each swab stick starting from the point of intended needle insertion and working outwards to prevent cross contamination. Alcohol 70% should be used to rinse the iodine off, and for maximal effect, it is important to allow the alcohol to evaporate, rather than swabbing it dry.

The use of polyurethane dressings has been shown to increase the colonization of skin by bacteria, mostly because of accumulation of sweat, which acts as a medium for bacterial growth [4, 5]. Hoffman and colleagues carried out an extensive review and meta-analysis to estimate the effect of transparent polyurethane film on central venous catheter tip infections [6]. They concluded that there was a significantly increased incidence of catheter-tip related infections with the use of polyurethane dressings. Changing the dressings more frequently would decrease the incidence of infection, but would certainly add to the cost of site care. Although this work was performed on central and peripheral i.v. catheters, the principles of colonization of skin and catheter by bacteria are similar. Additionally, with the high ambient temperatures of delivery suites and neonatal areas, the mother is more prone to sweating under a polyurethane film. The collection of sweat and high temperatures in turn would lead to an increased rate of bacterial cell division and add to the risk of catheter-related infections. Therefore, we recommend that polyurethane dressings should not be used on extradural catheter sites, especially when the catheter is likely to be used for periods greater than 24 h.

Sir,—Drs Kitching and Rice describe an interesting case of puerperal extradural abscess after normal delivery without extradural analgesia. A similar case was described by Male and Martin [1], who reported an extradural abscess that developed 6 days after normal delivery in a 22-yr-old woman who also had not received extradural analgesia. This patient had been admitted 10 days before delivery suffering from infective hepatitis with hepatocellular dysfunction and jaundice, whereas the patient described by Drs Kitching and Rice was presumably healthy.

I agree that it is possible for an extradural abscess to occur after extradural catheterization without a causal relationship existing. However, I would emphasize several points. The incidence of spontaneous extradural abscess in the general hospital population is estimated at 0.2–1.2 per 10000 which, indeed, is greater than the reported incidence of extradural abscess after lumbar extradural analgesia in obstetric patients, as pointed out by Drs Kitching and Rice. However, these populations are not equivalent. Closer inspection of reports within the general population demonstrates a high incidence of co-existing chronic disease, which is a risk factor for compromised immunity, and a predilection for the older age group, the majority of cases being patients older than 50 yr [2, 3]. In contrast, the average parturient is young and relatively healthy compared with the general population. Therefore a direct comparison of relative incidence between the obstetric population and the general population is inappropriate and statistically unsound.

I believe there is strong evidence of a causal relationship between the use of extradural anaesthesia and the development of an extradural abscess in our patient. This is supported by a close temporal relationship, correspondence of the location of the abscess and the site of extradural catheter insertion, and growth of the likely infective organism from a skin lesion at the puncture site.

Whilst Drs Kitching and Rice have demonstrated that extradural abscess can develop in the puerperium without obvious cause, I believe that extradural catheterization remains a risk factor for development of this serious condition in obstetrics and in other specialties, and would reiterate the importance of meticulous aseptic technique when performing these procedures.

Drs Vasdev and Leicht make pertinent comments regarding aseptic technique for extradural catheter insertion. However, I would draw to attention possible neonatal complications that may arise from maternal transdermal absorption of iodine from iodine-containing skin disinfectants. Neonatologists in our institution have shown recently that mothers exposed to topical iodine-containing antiseptics immediately before delivery had concentrations of iodine in their breast milk twice those of non-exposed mothers, and that this appeared to be linked to an increased incidence of transient neonatal hypothyroidism [4]. Iodine absorption would probably be minimized by the practice of rinsing off the iodine with 70% alcohol as recommended by Vasdev and Leicht, but in our delivery suite it is now policy to avoid completely the use of iodine-containing skin disinfectants.

We have favoured polyurethane dressings such as Tegaderm (3M) as dressings for extradural catheter sites because of their excellent fixation properties. Vasdev and Leicht cite evidence that these dressings may increase bacterial colonization, which indeed is of concern; we are currently reappraising usage in our practice.

THE LARYNGEAL MASK AND INTRAOCULAR SURGERY

Sir,—We were interested in the article of Lamb, James and Janicki on the effect of the laryngeal mask airway (LMA) [1] on intraocular pressure [2]. In their conclusion, the authors mentioned the potential risk of loss of airway control with the LMA during general anaesthesia for intraocular surgery. This risk is not theoretical, but a practical disadvantage of the method, as the anaesthetist does not have access to the patient's airway during surgery.

We describe two patients who recently underwent intraocular surgery under general anaesthesia (thiopentone, fentanyl, enflurane in an oxygen–nitrous oxide mixture and vecuronium). In both patients, insertion of the LMA was easy and resulted in a tight seal, which allowed mechanical ventilation (with peak inspiratory pressure less than 15 cm H_2O) [3]. The LMA was secured with adhesive strips. The surgical procedure for the first patient was initially uneventful, but the LMA was displaced slightly toward the end of the procedure. This resulted in a massive gas leak that led to a dramatic decrease in the expiratory tidal volume (less than 100 ml). Airway control was resumed temporarily by pushing down the LMA, but the leak recurred almost immediately. The LMA was then held in place by the anaesthetist's hand under the drapes and this allowed completion of the procedure. Hypoxia was not detected by pulse oximetry. Recovery was uneventful. In the second patient, a gas leak became evident before the beginning of the procedure, but after drapes, instrumentation and microscope were in place. Because expiratory flow was not detected in the breathing system, the drapes were removed hurriedly. The LMA was removed, the patient's lungs were ventilated using a face mask, additional thiopentone (150 mg) given i.v. and the trachea intubated. Hypoxia was not detected. In both patients there were no harmful consequences.

We had chosen to control the airway during general anaesthesia for intraocular surgery with the LMA because, as Lamb, James and Janicki have shown, this could blunt any increase in intraocular pressure. However, a minor incident (displacement of the LMA) could be transformed into a potentially disastrous accident. In our opinion, the inability of the anaesthetist to gain convenient control of the patient's airway during the procedure is a major hazard. Because of our experience, we have discontinued the use of an LMA for airway control in intraocular surgery.

BRAIN PARTIAL PRESSURES OF ISOFLURANE AND NITROUS OXIDE

Sir,—We read with interest the article by Dr Thornton and colleagues [1], but wish to comment on the methods used. Thornton's group used isoflurane or nitrous oxide, changed randomly in three consecutive 10-min periods. They do not state which anaesthesia system or what fresh gas flows they used.

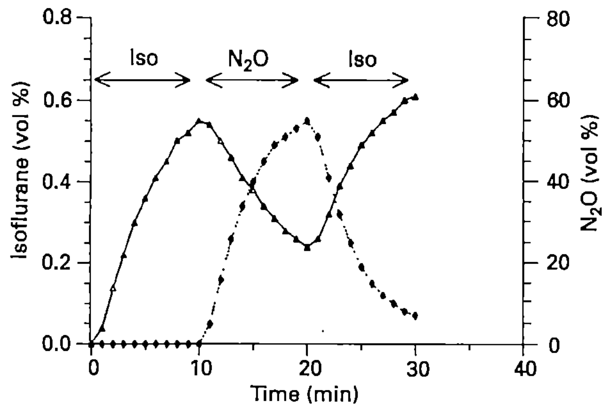

FIG. 1. Computer simulation of the brain partial pressures of isoflurane (△) and nitrous oxide (◆) during three 10-min periods in which either isoflurane (0.65–0.70 % end-tidal) or nitrous oxide (60–65 % end-tidal) was administered. Time = Time after beginning of anaesthesia. Iso = Isoflurane.

We have simulated an isoflurane–nitrous oxide–isoflurane anaesthesia period as described by Thornton and colleagues, with the GUS computer simulation program (Gas Uptake Simulation, iMedEd Inc, Phoenix, Arizona, U.S.A.) using a circle system and fresh gas flows of 12 litre min^{-1}. We agree that, when changing from isoflurane to nitrous oxide after the first 10-min period, stable end-tidal nitrous oxide values can be obtained within 5 min, after which the end-tidal partial pressure of isoflurane would not be less than 5 % of the initial value as stated by Dr Thornton and colleagues, but 0.23 vol % decreasing to 0.15 vol % at the end of the nitrous oxide period. Even with fresh gas flows of 20 litre min^{-1}, the residual end-tidal isoflurane washout from the brain would be even slower (fig. 1). Five minutes after the change from isoflurane to nitrous oxide, the brain partial pressure would be 0.38 vol %, decreasing to 0.24 vol % at the end of the nitrous oxide period. When, as in the first 10-min period, the end-tidal concentration of isoflurane is changed from 0 to approximately 0.70 vol %, a 10-min equilibration period does not produce stable brain partial pressures of isoflurane.

We would recommend longer equilibration periods in order to obtain stable conditions before measurements are performed.

Sir,—Thank you for inviting us to reply to the interesting letter from Drs Petersen-Felix and Zbinden. We have used a similar program, Narkup [1], which was produced at Northwick Park, to reproduce exactly the brain concentrations shown in their figure, when the alveolar concentrations of isoflurane and nitrous oxide were maintained at 0.6 % and 60 %, respectively. Clearly, both these programs use, for modelling of the "brain compartment", blood flow, mass and partition coefficient based on whole brain values. This is a good example of the need to know exactly what assumptions are made in pharmacokinetic models. When Narkup is re-run using, for example, assumptions that the effect compartment is in the cerebral grey matter (40 % of the brain), with a high proportion of the blood flow (say 70 %), then brain concentrations are stable for the whole of the test periods. Of course, we have no means of knowing if the above assumptions are true, but the writers of each program also do not know.

The end-expiratory concentrations of both gases were measured directly either by the Capnomac, or by a mass spectrometer in both our 1992 paper, and a previous study which used the same methodology [2]; in both studies, end-expiratory concentration had decreased to less than 5 % of the original concentration before the test period for the next gas. The anaesthetic was delivered from a Manley MP3 (non-rebreathing) as a circle system would have been inappropriate to produce the rapid changes in concentration that we needed. Again, any computer modelling would be dependent on assumptions about minute volume and cardiac output.

The particular point about the three-period statistical construction that we chose [3] is that it effectively eliminates errors which are caused by carry-over from one period to another.

HYPERTONIC SOLUTIONS IN MASSIVE HAEMORRHAGE

Sir,—We read with interest the case report by Dr Ngan Kee and transfusion by Donaldson, Seaman and Park [1] and would commend the authors on providing the reader with an excellent practical approach to the initial management of the acutely bleeding, hypovolaemic patient. However, we feel that a discussion on the crystalloid/colloid controversy should also now include some comment on the use of hypertonic solutions.

As the authors state, the success of initial resuscitation in the acutely hypovolaemic patient depends upon speed and adequacy of repletion. There has been increasing interest in the use of hypertonic solutions in the prehospital management of patients with traumatic hypovolaemic shock [2, 3]. The advantage of hypertonic over isotonic solutions in early resuscitation is that adequate resuscitation can be accomplished rapidly with small volumes through peripheral i.v. lines until conventional fluid therapy can be initiated. The smaller volume of fluid may also reduce complications related to dilutional coagulopathy and thermal stress. Hypertonic saline–Dextran 70 has been shown to improve mean arterial pressure, cardiac output, oxygen delivery and urine output and to increase survival compared with Ringer's lactate solution in severely traumatized patients [3].

Hypertonic solutions are still at an early stage of clinical investigation and further work is required before their role in fluid resuscitation is evaluated fully [4, 5]. The anticipated problems of acute hypernatraemia, hypervolaemia and venous injury have not materialized in the studies published so far [4].

We would suggest that in acute massive haemorrhage where venous access may be limited and rapid restoration of arterial pressure is required, there may be a role for hypertonic solutions. We would be interested in the authors' views on this subject.

Sir,—We are grateful to Drs Brimacombe and Berry for pointing out the omission of a discussion about hypertonic solutions. These authors have eloquently stated the advantages for hypertonic solutions and I agree with them. However, as they say, these solutions are still at an early stage of clinical investigation and I would further agree that more work is needed before they can be recommended routinely.

METAL PARTICLE GENERATION CAUSED BY THE COMBINED SPINAL–EXTRADURAL TECHNIQUE

Sir,—Recent letters in this journal [1, 2] have raised the question of potential damage to spinal or extradural needles when the needle-through-needle combined spinal–extradural technique is used. It has even been suggested that metal particle generation may arise because of this method [3].

Portex Ltd would like to take the opportunity to inform clinicians of an independent evaluation conducted to investigate this issue [4]. The aims of the study were: to assess any damage to the spinal and extradural needles produced by this technique; and to determine if the technique produces metal particulate contamination.

The trial tested the technique against different variables which could occur in clinical practice: two types of 26-gauge spinal needle with different tip profiles (lancet or pencil point); two different sizes of Portex Tuohy needles (16- and 18-gauge); two different rotations of the spinal needle during insertion (0° and 360°).

Each type of spinal needle was inserted through a Tuohy needle as during the needle-through-needle technique. A new spinal and extradural needle set was used in each case. When the lancet version was tested, it was introduced with the leading edge "running along" the base of the Tuohy curve in order to maximize any possible scraping effect.

Five millilitre of 0.45–0.8 µm-filtered sterile saline was flushed through the Tuohy needle under test and collected on a 0.45-µm membrane filter. A control sample of saline was taken also. Each membrane was examined under an Olympus BH binocular light microscope with × 10 objective. Any particles present were counted and sized.

Identification of any particles found on the membranes was made by energy dispersive x-ray analysis (EDX) in conjunction with a scanning electron microscope: the electron beam in the microscope strikes a surface and generates x-rays which have energy levels characteristic of the chemical elements present in the surface. The x-rays are detected and plotted out as energy level spectra which carry peaks which may be related unambiguously to specific elements. The technique is semi-quantitative, in that peak heights give an indication of the amount of each element present.

Stainless steel particles are easily recognized using EDX analysis, by their high chromium content. Both the extradural and spinal needles are made from medical grade stainless steel; however, none of the spectra generated indicated the presence of stainless steel particles.

The study showed no evidence to support the supposition that metal particles are produced as a consequence of utilizing the needle-through-needle technique.

Subsequent examination of both spinal and Tuohy needle tips showed no damage attributable to the technique.

FRACTIONAL UTILIZATION OF FRESH GAS BY BREATHING SYSTEMS WITHOUT CARBON DIOXIDE ABSORPTION

Sir,—We have been following with interest the articles by Drs Beatty, Meakin and Healy and their colleagues [1–3] concerning analysis of an Ohmeda EAR system, as we ourselves are analysing the fresh gas utilization of breathing systems without carbon dioxide absorption. The authors of these articles have termed this "fractional utilization" (Fu) of fresh gas. The fresh gas utilization of any system has to be calculated as the fraction of the fresh gas delivered to the patient against the total fresh gas flow into the system. This is independent of patient characteristics and is determined only by the physical characteristics of the system.

We have been calculating the fresh gas utilization of breathing systems without carbon dioxide absorption by first calculating the fraction of fresh gas that does not reach the patient, but is wasted in the system. This fresh gas wastage is calculated using the equation:

$$\frac{P\bar{\mathrm{E}}\mathrm{t}_{\mathrm{CO}_2} - P\bar{\mathrm{E}}\mathrm{v}_{\mathrm{CO}_2}}{P\bar{\mathrm{E}}\mathrm{t}_{\mathrm{CO}_2}} \qquad (1)$$

where $P\bar{\mathrm{E}}\mathrm{t}_{\mathrm{CO}_2}$ = mean expired carbon dioxide tension at the tracheal tube end of the system; $P\bar{\mathrm{E}}\mathrm{v}_{\mathrm{CO}_2}$ = mean expired carbon dioxide tension at the valve end of the system.

The change in the mean expired carbon dioxide tension at the valve end of the system is caused only by dilution of the expired gas by the fresh gas that has come out of the system without reaching the patient.

This equation is similar to that used for calculating the physiological deadspace, in which the fraction of gas that has diluted the ideal alveolar gas is calculated:

$$\frac{V\mathrm{D}}{V\mathrm{T}} = \frac{P\mathrm{a}_{\mathrm{CO}_2} - P\bar{\mathrm{E}}_{\mathrm{CO}_2}}{P\mathrm{a}_{\mathrm{CO}_2}} \qquad (2)$$

The fresh gas utilized by the system (Fu) is the fraction of fresh gas that is not wasted, but reaches the patient and is calculated as:

$$F\mathrm{u} = 1 - \frac{P\bar{\mathrm{E}}\mathrm{t}_{\mathrm{CO}_2} - P\bar{\mathrm{E}}\mathrm{v}_{\mathrm{CO}_2}}{P\bar{\mathrm{E}}\mathrm{t}_{\mathrm{CO}_2}} \qquad (3)$$

Rewriting the above equation, we get

$$F\mathrm{u} = \frac{P\bar{\mathrm{E}}\mathrm{v}_{\mathrm{CO}_2}}{P\bar{\mathrm{E}}\mathrm{t}_{\mathrm{CO}_2}} \qquad (4)$$

The value $P\bar{\mathrm{E}}\mathrm{t}_{\mathrm{CO}_2}$ can be taken as the same as the end-tidal carbon dioxide tension. $P\mathrm{Ev}_{\mathrm{CO}_2}$ can be measured easily by attaching a corrugated tube and an open-ended reservoir bag to the scavenging port of the valve and sampling continuously from the tail end of the bag.

The authors of the above mentioned articles have used complicated calculations from data collected by equally complicated means to derive the fractional utilization of fresh gas of the EAR system. They have analysed the fraction of fresh gas that takes part in the alveolar gas exchange by using the equation:

$$F\mathrm{u} = \frac{\dot{V}_{\mathrm{CO}_2}}{\dot{V}\mathrm{F} \times F\mathrm{A}_{\mathrm{CO}_2}} \qquad (5)$$

This fraction is not determined by the physical characteristics of the breathing system, but by many factors such as age of the patient, smoking, lung pathology, $\dot{V}/\dot{Q}$ mismatch. This should be termed the fractional utilization by the patient, and not by the system.

The authors have shown how variations in patient utilization adversely affect the calculated Fu of the system, in their studies using the EAR system in adults, children and lung models.

In their recently published article [4], they seem to have understood the problems encountered by their approach and have tried to correct it by coining a new term—fractional delivery of fresh gas (Fd)—which is actually the same as the fractional utilization of fresh gas by the system. Here again, they have used a complicated equation:

$$F\mathrm{d} = \frac{\dot{V}_{\mathrm{CO}_2}}{\dot{V}\mathrm{F} \times F\bar{\mathrm{E}}'_{\mathrm{CO}_2}} \qquad (6)$$

They have derived $\dot{V}_{CO_2}$ by accurately measuring the fresh gas flow and multiplying it by $F\bar{\mathrm{E}}\mathrm{v}_{CO_2}$. $F\mathrm{E}'_{CO_2}$ is taken to be the same as the end-tidal carbon dioxide concentration.

Expanding equation (6) we get:

$$Fd = \frac{\dot{V}\mathrm{F} \times F\bar{\mathrm{E}}\mathrm{v}_{CO_2}}{\dot{V}\mathrm{F} \times F\mathrm{E}'\mathrm{t}_{CO_2}} \tag{7}$$

$$= \frac{P\bar{\mathrm{E}}\mathrm{v}_{CO_2}}{P\bar{\mathrm{E}}\mathrm{t}_{CO_2}} \tag{8}$$

It is apparent that equations (4) and (8) are the same. These values can be obtained easily using the same side-stream analyser; accurate measurement of the fresh gas flow is not necessary.

In view of this simplicity, the authors should change their equation to the simpler one. Using two terminologies is confusing and we think that they should use the well accepted terminology of fractional utilization of fresh gas (*F*u) of the system.

4. Beatty PCW, Meakin G, Healy TEJ. Fractional delivery of fresh gas: a new index of efficiency of semiclosed breathing systems. *British Journal of Anaesthesia* 1992; **69**: 474–477.

Sir,—Thank you for the opportunity of replying to the letter by Drs Ravishankar and Chatterjee.

The purpose of our paper [1] was to draw attention to the fact that fractional utilization of fresh gas (*F*u) with a semi-closed breathing system is not constant, but varies with the arterial to end-tidal carbon dioxide partial pressure difference of the patients being studied. We noted that if end-tidal carbon dioxide measurements were used in place of arterial measurements in the equations for *F*u, a different parameter resulted which was independent of patient factors. This we termed fractional delivery of fresh gas (*F*d), as it was a measure of the proportion of fresh gas delivered to the patient's alveolar compartment, whether or not it took part in gas exchange.

Drs Ravishankar and Chatterjee have used a different approach than ours to arrive at an equation for calculating breathing system efficiency from measurements of end-tidal and mixed vented carbon dioxide concentrations (equations (1)–(4)). However, as arterial measurements of carbon dioxide are not used, we suggest that the efficiency index they have calculated is fractional delivery and not fractional utilization of fresh gas. This explains why, when simplified, both their equation (3) and ours for *F*d (6) yield the same result (8).

BOOK REVIEWS

Anesthésie et Analgésie en Obstétrique. Collection d'Anesthésiologie et de Réanimation, Volume 33. Edited by P. Schoeffler. Published (1992) by Masson. Pp. 254; indexed; illustrated. Price FFr. 290.

This volume (No. 33) of the *Collection d'Anesthésiologie et de Réanimation* is the latest addition to the range of text books on obstetric analgesia and anaesthesia. It consists of 13 chapters written by 21 contributors and is divided into four sections.

The first section covers the preoperative anaesthetic assessment of the pregnant woman and the specific problems related to the physiological effects of pregnancy.

The second section, Anaesthetic Management Before and During Pregnancy, consists of four chapters discussing management for oocyte retrieval and *in vitro* fertilization, non-obstetric surgery, fetal surgery and termination of pregnancy.This section is well written and is of current interest because of the introduction of pharmacological methods of terminating early pregnancy. The chapter on anaesthesia and monitoring for fetal intervention discusses the anaesthetic, tocolytic and surgical management to maximize fetal neonatal survival.

The third section, Anaesthesia and Analgesia for Labour, Comprises four chapters which are concise and clear. The chapter on the anaesthetic implications of co-existing diseases in the parturient is excellent and well referenced.

The last section, an overview of the management of maternal and fetal complications, consists of three chapters. The management of pregnancy-induced hypertension and of haemorrhage is discussed thoroughly.

Although this is a relatively small book, it should prove useful to all French speaking anaesthetists. Many of the references are as recent as 1990/91.The volume can be recommended as a useful basis and reference source for those with an interest in obstetric anaesthesia.

Transesophageal Echocardiography. Edited by F. M. Clements and N. P. de Bruijn. Published by Little, Browne and Co., Boston, Toronto, London. Pp. 163; indexed; illustrated. Price £65.

Conventional transthoracic echocardiography requires considerable operator skill to identify the necessary windows to the heart. Imaging from the chest wall is frequently unsuccessful in patients with emphysema and obesity. In addition, the distance from the transducer located on the chest wall to the left atrium and left ventricle may limit the diagnosis of atrial septal defects, the detection of atrial thrombi and the source of systemic embolization, and the assessment of mitral valve structures and function.

The technical difficulties involved in positioning the transducer in the oesophagus, adjacent to the left chambers, was overcome in 1981 by Hanrath and colleagues in West Germany, when an oesophageal, phased array transducer, capable of two-dimensional imaging, was developed by housing the transducer inside a flexible gastroscope from which the fibreoptics were removed. The development of Doppler colour flow mapping to visualize blood flow velocity within the heart and surgical interest in mitral valve repair were two catalysts in the mid 1980s responsible for the impressive growth and interest in intraoperative transoesophageal echocardiography (TOE).

The technique of TOE entered the sphere of anaesthetic practice in 1985. Drs de Bruijn and Clements from Duke University Medical Centre, Durham, North Carolina, were the first to review comprehensively the basic concepts of this new technology in the anaesthetic literature; furthermore, they edited the Society of Cardiovascular Anesthesiologists' monograph on the intraoperative use of echocardiography. It was inevitable that they would provide a basic text to highlight the technical applications and limitations of TOE. Drs Clements and de Bruijn's first edition *Transesophageal Echocardiography* combines the features of a textbook and an atlas. The 158 pages of text include 10 chapters featuring the development of transoesophageal imaging; two dimensional echocardiography: creating an image; Doppler echocardiography; anatomical orientation to oesophageal imaging; technique of transoesophageal imaging in awake and anaesthetized patients; intraoperative monitoring for regional wall motion abnormalities; evaluation of left ventricular size and function; interventional echocardiography and the mitral valve, the aorta and aortic valve; imaging the right and left atria and atrial and ventricular septal defects. The text in each chapter is accompanied by illustrations, figures, flow charts, line drawings and reproductions of TOE monitor views.

Transoesophageal echocardiography is a technology which spans the spectrum of cardiology, anaesthesia and cardiac surgery. The role of TOE in anaesthetic practice and the educational and technical experience necessary to undertake the procedure continue to evolve, but differ from institution to institution and from year to year. The extent and adequacy of experience with echocardiography is a major concern in 1993 because non-cardiologists, including anaesthetists and surgeons, are currently using the technology for intraoperative clinical decision making with little or no formal training. The mechanisms whereby Cardiac Anaesthesia Fellows in Duke University obtain the satisfactory experience proposed by the American Society of Echocardiography Committee for Physician Training in Echocardiography is outlined briefly in chapter 1.

This reviewer is aware of no better explicit and succinct descriptions of the basic concepts of echocardiography and Doppler colour flow imaging than are presented in chapters 2 and 3. The authors assume the reader has no previous knowledge of these topics. The principles of ultrasound frequency and reflection, transducer design and image processing are described, with additional practical details for the operator such as gain control, depth and width controls, grey scale adjustment, time–gain–compensation (TGC) control and the controls for pulsed-wave Doppler and Doppler colour flow imaging. The authors, fortuitously, featured the Hewlett–Packard console and transducer—the product which has achieved the most extensive anaesthetic application. The artefacts to which the technology is subject and such phenomena such as "echo drop out" and "frequency aliasing" are highlighted.

Chapters 4 and 5 describe the technique of TOE imaging in awake and anaesthetized patients, with special emphasis on how to obtain the base of the heart short axis view, the long axis four-chamber view and the transgastric short axis image of the left and right ventricles. The indications, contraindications and complications of TOE are discussed in detail.

The application of TOE in anaesthetic practice will vary depending on individual interest and practice. Many anaesthetists would welcome a simple-to-use echocardiographic monitoring system which would allow non-invasive assessment of global left ventricular function and regional wall motion. The application of TOE-derived regional wall motion abnormalities in the detection of intraoperative myocardial ischaemia is addressed in chapter 6. If I have any reservations concerning this first edition, it would be that the authors did not balance their interest in TOE as a diagnostic tool with, perhaps, its more useful anaesthetic relevance as a non-invasive monitoring technique. For example, segmental wall motion scoring systems are referred to, but not described. Somewhat superficial comparisons were made between the sensitivity of regional wall motition abnormalities and ECG-derived ST segment and pulmonary artery occlusion pressure changes. The techniques to assess left ventricular end-diastolic area as an index of preload, left ventricular area ejection fraction as an index of left ventricular performance and left ventricular wall stress are described, but no data are provided about validation studies of these measurements and their potential intraoperative and critical care applications. Also, no references were provided for this and some other chapters.

The interest of the authors in transoesophageal echocardiography as a diagnostic tool was highlighted by the statement... "the single most useful application of TEE is the study of mitral regurgitation". The role of Doppler colour flow imaging in the evaluation and quantification of mitral regurgitation, the detection of paravalvular leaks and the adequacy of surgical results are all discussed and illustrated in impressive detail. Similarly, a comparative evaluation is provided of TOE, as compared with angiography and computed tomography in the evaluation of dissection of the ascending and descending aorta. That anaesthetists could, or should, be involved in these diagnostic deliberations is a matter of debate.

The application of transoesophageal echocardiography in clinical practice has shown impressive growth and striking regional variations over the past decade. TOE has now become a mandatory integral component of mitral valve repair in many North American institutions. Individual anaesthetists in North American and continental Europe have increasingly used TOE as a monitoring adjuvant during aortocoronary bypass surgery, major vascular surgery and posterior fossa surgery with the patient in the sitting position. In contrast, United Kingdom anaesthetists, whether for economic considerations or because of adherence to more traditional "finger on the pulse" clinical assessment, have tended to ignore this new technology and British experience, to date, has been mostly confined to cardiological studies in awake patients. Notwithstanding, this first edition of *Transesophageal Echocardiography* by Clements and de Bruijn is a must for any practitioner—cardiologist, cardiac surgeon or anaesthetist—involved in the management of patients undergoing major cardiac or vascular surgery or critical care medicine.

A. J. Cunningham

The Complete Recovery Room Book. By A. Hatfield and M. Tronson. Published by Oxford University Press, Oxford. Pp. 369; indexed; illustrated. Price £17.50.

This book is presented as a comprehensive reference manual for recovery rooms, and is a further addition to recently published texts on the immediate postoperative care of surgical patients. It comprises three main sections: "Setting up a Recovery Room", "Patient Care" and "Basic Physiology and Useful Data".

The opening chapters of the first section deal with the physical design and staffing of the recovery room. These may be of interest to some readers, but is probable that the third chapter will be more useful, as it gives an excellent functional description of the basic items of equipment used by recovery room staff. The closing chapter in this section is a welcome appraisal of the importance of preventing cross-infection in the recovery room.

The second section, "Patient Care", is an exposition of the immediate care of patients after operation. This is well written and comprehensive. For example, the chapter "Routine recovery room procedures" is an excellent and practical introduction to the subject, although I cannot accept that awareness under general anaesthesia is a "daily dilemma" as described! Other chapters deal with the assessment of patients, emergencies, monitoring, analgesia, i.v. fluids, bleeding problems and drugs and infusions. This section of the book would be very useful for teaching, and it would be easy to base a tutorial course on it.

The third section of the book is a concise description of cardiovascular and respiratory physiology. The Appendices are useful and include an explanation of abbreviations used in hospitals, a description of pulmonary artery flotation catheters, procedures for assessing patients (Glasgow coma scale), and suggestions for "emergency" trays to be used, for example, for the treatment of anaphylaxis.

It is a little difficult to anticipate who will find this book most attractive. The problem is that, in certain places, the approach is very simplistic (e.g. "the recovery room links the theatres to the wards"), which will not appeal to doctors, but as a whole the book does contain a considerable amount of detailed information. From their Preface, it seems that the authors intended it to be used for the teaching of nursing staff, and I would suggest that it would be best used as a core textbook for an introductory course on recovery room techniques.

I. Power

Essay Plans for Anaesthesia Exams. By M. Z. Michel, N. W. Goodman and A. R. Aitkenhead. Published by Churchill Livingstone, Edinburgh. Pp. 191; indexed. Price £15.95.

The authors of this short book state that it originated from the preparation of one of the authors for the Part 3 examination. He made essay plans for previous, and predicted, questions and these plans form the basis of the present volume. The book is intended for candidates for the Parts 1 and 3 of the F.R.C.A. examination, although I expect that its main appeal will lie with those taking Part 3. It contains outline answers to 75 questions, with advice on common errors.

The book is divided into seven chapters indicating general areas of interest such as anatomy and regional anaesthesia, intensive care, specialized general anaesthesia and questions based on physiology and pharmacology. Within each chapter, between eight and 16 outline answers to specific questions are provided. The approach is didactic, with clear advice as to what is correct and what is incorrect. I found myself in agreement with most of the outlines provided, although in my areas of specific interest there are some small factual errors. I doubt if they would influence the examination mark awarded, but they do illustrate the point that it is no longer possible for an author, or three authors, to keep up with current knowledge in all areas of anaesthetic practice. Indeed, many of us who teach extensively for the examinations adopt a two-handed approach. We teach the safe examination answer and the current state of knowledge; regrettably there is often a considerable gulf between the two.

I expect that this book will be successful, as it fulfils a need of many examination candidates. I hope that the essay questions remain an important part of our examination structure. Anaesthetists must be able to demonstrate that they can apply their knowledge logically and sensibly to common clinical problems. Michel, Goodman and Aitkenhead will help many candidates to improve their written presentation.

SUBJECT INDEX

ABC of Transfusion, 2nd Edn, Contreras, M., (editor), (*R*) 495

Acid–base equilibrium, Changes in blood lactate, total body oxygen delivery and consumption during liver transplantation, Carrera, J., *et al.*, (*ESA*) A.77

Acid–base equilibrium, metabolic acidosis, Acute haemodynamic effect of sodium bicarbonate in canine respiratory or metabolic acidosis, Nishikawa, T. 196–200

——, Haemodynamic and metabolic consequences of aortic occlusion during abdominal aortic surgery, Whalley, D. G., *et al.* 96–98

Acid–base equilibrium, pH, Measurement of sigmoid intramural pH during orthotopic liver transplantation, Auroy, Y., *et al.*, (*ESA*) A.76

Acid–base equilibrium, respiratory acidosis, Acute haemodynamic effect of sodium bicarbonate in canine respiratory or metabolic acidosis, Nishikawa, T. 196–200

——, An alternative method of increasing $P\text{CO}_2$ using apnoea and continuous positive airway pressure, Karlsten, R., *et al.* 411–413

Adductor pollicis, Anq 9040: effect of twice the ED$_{95}$ dose, Munday, I. T., *et al.*, (*ARS*) 480P

——, Can repetition of high frequencies stimuli alter the value of 50 and 100 Hz tetanic fade during vecuronium induced neuromuscular blockade? Baurain, M. J., *et al.*, (*ESA*) A.135

——, Comparison of the onset of depolarizing *vs* non-depolarizing block after early tourniquet release in the isolated forearm, Hood, J. R., *et al.*, (*ARS*) 480P

——, Concentration–effect relationship at the vocal cords and the adductor pollicis following rocuronium administration, Plaud, B., *et al.*, (*ESA*) A.141

——, Effect of isometric thumb preload on the evoked compound muscle action potential, Kalli, I. 92–93

——, Monitoring the onset of neuromuscular blockade at the orbicularis oculi can predict good intubating conditions when using 2 × ED$_{95}$ of atracurium, Debaene, B., *et al.*, (*ESA*) A.142

——, Potency estimation of mivacurium: comparison of two different modes of nerve stimulation, Maddineni, V. R., *et al.* 694–695

——, Recovery of atracurium and vecuronium neuromuscular block in the isolated forearm, Law Min, J.-C., *et al.*, (*ARS*) 480–481P

——, Tetanic fade during recovery from vecuronium block: comparison of systemic and isolated forearm administration, Campkin, N. T. A., *et al.* 581–582

Adult Respiratory Distress Syndrome, Artigas, A., *et al.*, (editors), (*R*) 117

Age factors, An investigation into the effect of passive and active cutaneous warming devices on intraoperative body temperature in elderly patients, Bennet, J., *et al.*, (*ESA*) A.73

——, Anesthesia for patients ⩾ 90 years of age in emergency hip surgery, Eleftheriadis, S., *et al.*, (*ESA*) A.3

——, Comparison of infusion rates of three i.v. anaesthetic agents for induction in elderly patients, Berthoud, M. C., *et al.* 423–427

——, Different rates of injection of propofol, Goodman, N. W., (*C*) 383

——, Different rates of injection of propofol, Peacock, J. E., *et al.*, (*C*) 383–384

——, Effect of age, gender and anaesthetic technique on the pharmacodynamics of atracurium, Parker, C. J. R., *et al.* 38–41

——, Effect of age on the sensitivity of upper airway reflexes, Erskine, R. J., *et al.* 574–575

——, Effectiveness of core warming on net transfer of body heat across the skin, Kulkarni, P., *et al.*, (*ESA*) A.70

——, Fresh gas requirements of an enclosed afferent reservoir breathing system in anaesthetized, spontaneously breathing adults, Barrie, J. R., *et al.* 468–470

——, Incidence of post dural puncture headache in young adults by the use of the Sprötte needle: 300 patients, Descraques, C., *et al.*, (*ESA*) A.127

——, Ketamine does not prevent hypotension caused by induction of anaesthesia with propofol in elderly patients, Blockmans, D., *et al.*, (*ESA*) A.40

——, Lung function after vecuronium pretreatment in elderly patients, Mahajan, R. P., *et al.*, (*ARS*) 482–483P

——, Minimum alveolar concentration of sevoflurane in elderly patients, Nakajima, R., *et al.* 273–275

——, Safety of PCA in elderly, Santangelo, E., *et al.*, (*ESA*) A.206

——, Subarachnoid anaesthesia (SAA) and postoperative analgesia with bupivacaine (BV) plus fentanyl (FN) in geriatric patients, Fernandez, D., *et al.*, (*ESA*) A.131

——, The pharmacokinetics of rocuronium in pediatric patients: a pooled data analysis, Meistelman, C., *et al.*, (*ESA*) A.138

Airway, aerosol penetration, Penetration of an aerosol, produced by film atomization, through the carinal bifurcation, Inglis, T. J. J., *et al.* 527–531

Airway, anatomy, A new clinical score to predict difficult intubation, Arné, J., *et al.*, (*ESA*) A.1

——, Mathematical analysis of the upper respiratory tract from an anthropometric study, Janvier, G., *et al.* 186–191

Airway, infections, A new clinical score to predict difficult intubation, Arné, J., *et al.*, (*ESA*) A.1

——, Penetration of an aerosol, produced by film atomization, through the carinal bifurcation, Inglis, T. J. J., *et al.* 527–531

Airway, mucosa, Glycopyrronium prolongs topical anaesthesia of oral mucosa and enhances absorption of lignocaine, Watanabe, H., *et al.* 94–95

Airway, obstruction, Effects of PEEP on dynamic hyperinflation in patients with airflow limitation, Tan, I. K. S., *et al.* 267–272

——, The airway decides the anaesthetic approach before tracheal intubation, Vaughan, R. S., *et al.*, (*C*) 600

——, The airway decides the anaesthetic approach before tracheal intubation, Williamson, R., (*C*) 600

Airway, patency, Continuous spirometry: an aid in the intraoperative respiratory monitoring—case reports, Bardoczky, G., *et al.*, (*ESA*) A.55

Airway, pressure, Pressure exerted by the laryngeal mask airway cuff upon the pharyngeal mucosa, Marjot, R. 25–29

Airway, reflexes, Effect of age on the sensitivity of upper airway reflexes, Erskine, R. J., *et al.* 574–575

——, Effect of oral diazepam on the sensitivity of upper airway reflexes, Murphy, P. J., *et al.* 131–134

——, Effect of stopping smoking on upper airway reflexes, Erskine, R. J., *et al.*, (*ARS*) 478P

——, Measurement of the sensitivity of upper airway reflexes, Langton, J. A., *et al.* 126–130

——, Upper airway reflexes, Drummond, G. B., (*E*) 121–123

Alcohol, Delayed presentation of an extradural abscess in a patient with alcohol abuse, Nordström, O., *et al.* 368–369

Alcohol, withdrawal, Carbohydrate deficient transferrin: a new copredictor of alcoholism related postoperative complications? Heil, T., *et al.*, (*ESA*) A.88

Anaesthesia, audit, Adequate pain relief with epidural analgesia during labor: why are women still dissatisified? Hamza, J., *et al.*, (*ESA*) A.171

——, An audit of the incidence and costs associated with post operative nausea and vomiting (PONV) following major gynaecological surgery in an inpatient population, Morris, R. W., *et al.*, (*ESA*) A.2

——, Editorial II—the National Confidential Enquiry into Perioperative Deaths, Lunn, J. N., *et al.*, (*C*) 382

Anaesthesia, day-case, Comparison of alfentanil with suxamethonium in facilitating nasotracheal intubation in day-case anaesthesia, Alcock, R., *et al.* 34–37

——, Comparison of midazolam with propofol for sedation in outpatient bronchoscopy, Crawford, M., *et al.* 419–422

——, Comparison of recovery from anaesthesia induced in children with either propofol or thiopentone, Runcie, C. J., *et al.* 192–195

——, Propofol for tracheal intubation in paediatric outpatient anaesthesia, Montasser, A. M., (*ESA*) A.161

——, Use of alfentanil with propofol for nasotracheal intubation without neuromuscular block, Coghlan, S. F. E., *et al.* 89–91

Anaesthesia, dental, Comparison of alfentanil with suxamethonium in facilitating nasotracheal intubation in day-case anaesthesia, Alcock, R., *et al.* 34–37

Anaesthesia, depth, Validation of coherent frequency of the EEG as a measure of consciousness during anaesthesia, Munglani, R., *et al.*, (*ARS*) 483–484P

Anaesthesia, general, Fresh gas requirements of an enclosed afferent reservoir breathing system in anaesthetized, spontaneously breathing adults, Barrie, J. R., *et al.* 468–470

——, Hypoxic events after general anaesthesia in the recovery room, Degasperi, D., *et al.*, (*ESA*) A.59

——, Long-term backache after extradural or general anaesthesia for manual removal of placenta: preliminary report, Vickers, R. J., *et al.* 214–215

——, Metabolic effects of propofol and flunitrazepam given for sedation after aortic surgery, Moritz, F., *et al.* 451–453

——, Recruitment of atelectasis during general anaesthesia: a CT-study, Rothen, H. U., *et al.*, (*ESA*) A.53

——, Studies of gastric content: comparison of two methods, Søreide, E., *et al.* 360–362

Anaesthesia, geriatric, Anesthesia for patients $\geq$ 90 years of age in emergency hip surgery, Eleftheriadis, S., *et al.*, (*ESA*) A.3

——, Fentanyl or buprenorphine side effects in spinal anaesthesia, Foppoli, R., *et al.*, (*ESA*) A.132

——, Ketamine does not prevent hypotension caused by induction of anaesthesia with propofol in elderly patients, Blockmans, D., *et al.*, (*ESA*) A.40

——, Minimum alveolar concentration of sevoflurane in elderly patients, Nakajima, R., *et al.* 273–275

——, Subarachnoid anaesthesia (SAA) and postoperative analgesia with bupivacaine (BV) plus fentanyl (FN) in geriatric patients, Fernandez, D., *et al.*, (*ESA*) A.131

Anaesthesia, neurosurgical, Adrenaline-induced hypotension in neurosurgery, Phillips, S., *et al.* 687–688

——, Effect of esmolol *versus* lidocaine on intracranial pressure and haemodynamic responses to laryngoscopy and intubation, Samaha, T., *et al.*, (*ESA*) A.118

Anaesthesia, obstetric, A continuous subdural block, Collier, C. B., *et al.* 462–465

——, Addition of droperidol to patient-controlled analgesia: effect on nausea and vomiting, Williams, O. A., *et al.*, (*ARS*) 479P

——, Antepartum assessment for anaesthesia, Cody, M., *et al.*, (*C*) 116

——, Antepartum assessment for anaesthesia, Reynolds, F., (*C*) 116

——, Antepartum assessment for anaesthesia, Uncles, D. R., *et al.*, (*C*) 116

——, Best Quincke point needle for Caesarean section, Lyons, G., (*ESA*) A.174

——, Continuous subarachnoid infusion of 0.125% bupivacaine for analgesia during labour, McHale, S., *et al.*, (*C*) 701

——, Continuous subarachnoid infusion of 0.125% bupivacaine for analgesia during labour, Russell, R., (*C*) 699–700

——, Diclofenac and ketoprofen for pain treatment after elective Caesarean section, Rorarius, M. G. F., *et al.* 293–297

——, Effects of etomidate on the adrenocortical and metabolic adaptation of the neonate, Crozier, T. A., *et al.* 47–53

——, Extradural abscess in the postpartum period, Kitching, A. J., *et al.*, (*C*) 703

——, Extradural abscess in the postpartum period, Ngan Kee, W. D., (*C*) 704

——, Extradural abscess in the postpartum period, Vasdev, G. M. S., *et al.*, (*C*) 703–704

——, Headache—new needles and spinal anaesthesia for C. section, Thormann, F., *et al.*, (*ESA*) A.173

Complications, paralysis, Muscular paralysis and ventilatory failure caused by hyperkalaemia, Freeman, S. J., *et al.* 226–227

——, Spinal extradural abscess: pursuit of vigilance, Bromage, P. R. 471–473

Complications, phaeochromocytoma, Use of transoesophageal echocardiography to manage beta-adrenoceptor block and assess left ventricular function in a patient with phaeochromocytoma, Ryan, T., *et al.* 101–103

Complications, poisoning, The management of acute poisoning, Collee, G. G., *et al.* 562–573

Complications, porphyria, Xylometazoline and porphyria, Platt, N. D., (*C*) 491

Complications, pulmonary, Reassessment of bronchoalveolar lavage in the diagnosis of post traumatic pulmonary fat embolism, Mimoz, O., *et al.*, (*ESA*) A.180

——, Septic shock: effect of a goal-directed therapy on oxygen metabolism and serum cytokine levels, Martin, C., *et al.*, (*ESA*) A.189

Complications, pulmonary oedema, neurogenic, Adult respiratory distress syndrome after attempted strangulation, Murphy, P. G., *et al.* 583–586

Complications, regurgitation, Preoperative drinking does not affect gastric contents, Phillips, S., *et al.* 6–9

——, Regurgitation and the laryngeal mask airway, Brimacombe, J., *et al.*, (*C*) 381

——, Regurgitation and the laryngeal mask airway, Vanner, R. G., (*C*) 380–381

Complications, renal, Outcome for patients in intensive care with acute renal failure requiring dialysis, Ejlersen, E., *et al.*, (*ESA*) A.7

——, Prevention of acute tubular necrosis by volume loading in kidney transplantation, Mouquet, C., *et al.*, (*ESA*) A.82

——, Volume loading and hormonal factors in the prevention of acute tubular necrosis in kidney transplantation, Mouquet, C., *et al.*, (*ESA*) A.83

Complications, respiratory, Continuous spirometry: an aid in the intraoperative respiratory monitoring—case reports, Bardoczky, G., *et al.*, (*ESA*) A.55

Complications, respiratory depression, A comparison of midazolam and midazolam plus fentanyl for colonoscopy, Dupont, H., *et al.*, (*ESA*) A.9

Complications, septicaemia, Comparison of thoracic electrical bioimpedance and thermodilution for the measurement of cardiac index in patients with severe sepsis, Young, J. D., *et al.* 58–62

——, Comparison of two therapeutic strategies of septic shock, Martin, C., *et al.*, (*ESA*) A.190

——, Influence of N-acetylcysteine on O_2 consumption and gastric intramucosal pH in septic patients, Spies, C., *et al.*, (*ESA*) A.186

——, Influence of norepinephrine therapy on the oxygen supply and lactate extraction rate of the liver in the septic pig, Schäfer, R., *et al.*, (*ESA*) A.184

——, Molecular mediators and post-bacteraemic phase, Martínez Urionabarrenetxea, K., *et al.*, (*ESA*) A.187

——, Non invasive monitoring of CO_2 in patients with septic shock, Bodin, L., *et al.*, (*ESA*) A.191

——, Septic shock: effect of a goal-directed therapy on oxygen metabolism and serum cytokine levels, Martin, C., *et al.*, (*ESA*) A.189

——, The effect of dobutamine and norepinephrine on global and splanchnic O_2 consumption, Meier-Hellmann, A., *et al.*, (*ESA*) A.185

Complications, shivering, Effect of radiant heat on the metabolic cost of postoperative shivering, Sharkey, A., *et al.* 449–450

——, Fentanyl, as pethidine, inhibits post anaesthesia shivering, Alfonsi, P., *et al.*, (*ESA*) A.74

Complications, sinusitis, Incidence of bacterial maxillary sinusitis in critically ill patients with radiologic maxillary sinusitis, Bodin, L., *et al.*, (*ESA*) A.179

Complications, smokers, Effect of stopping smoking on upper airway reflexes, Erskine, R. J., *et al.*, (*ARS*) 478P

Complications, spontaneous excitatory movements, Spontaneous excitatory movements during recovery from propofol anaesthesia in an infant: EEG evaluation, Borgeat, A., *et al.* 459–461

Complications, stenosis, Dipyridamole-TEE and 24 h Holter-ECG as preoperative screening tests for coronary artery disease in patients with abdominal aortic aneurysm, Östman, M., *et al.*, (*ESA*) A.22

——, Does routine preoperative coronary angiography modify outcome after aortic surgery? Gosgnach, M., *et al.*, (*ESA*) A.6

——, Evaluation of haemodynamic indices of myocardial ischaemia in patients with coronary artery disease (CAD), Hohner, P., *et al.*, (*ESA*) A.23

——, Indications for coronary revascularisation in vascular surgical patients, Gosgnach, M., *et al.*, (*ESA*) A.5

——, Pulmonary and systemic vascular effects of isoproterenol, nitroglycerin and prostaglandin E1 early after cardiac operations in patients with pulmonary hypertension, Alvarez, J., *et al.*, (*ESA*) A.27

——, Sensitivity and specificity of mechanical and electrocardiographic myocardial ischaemia (MI) monitoring techniques, Hohner, P., *et al.*, (*ESA*) A.26

——, The use of the CUSUM plot for determination of myocardial ischaemia threshold during atrial pacing in patients with coronary artery disease, Reiz, S., *et al.*, (*ESA*) A.24

Complications, systemic lupus erythematosus, Anaesthetic implications of the anti-cardiolipin antibody syndrome, Menon, G., *et al.* 587–590

Complications, thrombosis, Anaesthetic implications of the anti-cardiolipin antibody syndrome, Menon, G., *et al.* 587–590

——, Aprotinin does not decrease surgical bleeding and could promote arterial thrombosis in the pig: a prospective randomized, blind, study, Samama, C. M., *et al.*, (*ESA*) A.100

——, Inhibition of increase of blood thromboxane concentration by acetylsalicylic acid after release of tourniquet in lower extremity operations, Ojanen, R., *et al.*, (*ESA*) A.94

Complications, trauma, Diagnosis of aortic rupture by transesophageal echocardiography (TEE), Goarin, J. P., *et al.*, (*ESA*) A.193

——, Evaluation of systematic TEE in patients suspected of blunt chest trauma, Catoire, P., *et al.*, (*ESA*) A.192

——, Jugular bulb metabolic monitoring during hyperventilation in severe head trauma patients, De Deyne, C., *et al.*, (*ESA*) A.106

——, Reassessment of bronchoalveolar lavage in the diagnosis of post traumatic pulmonary fat embolism, Mimoz, O., *et al.*, (*ESA*) A.180

——, Sufentanil increases intracranial pressure in patients with head trauma, Albanese, J., *et al.*, (*ESA*) A.107

——, Systemic gas embolism in pulmonary contusion diagnosed by transesophageal echocardiography, Saada, M., *et al.*, (*ESA*) A.194

——, The haemostatic response to surgery and trauma, Murphy, W. G., *et al.* 205–213

Complications, ultrasound, Endocardial endothelium modulates *in vivo* left ventricular performance, De Hert, S. G., *et al.*, (*ESA*) A.47

Computers, A national database for intensive care medicine in Sweden, Karling, M., (*ESA*) A.8

Conduction Blockade for Postoperative Analgesia: Mechanisms and Management, McClure, J. H., *et al.*, (editors), (*R*) 239

Cough, Postoperative laryngeal function assessed by tussometry, Lamb, J. M., *et al.*, (*ARS*) 478–479P

Diabetes, Muscular paralysis and ventilatory failure caused by hyperkalaemia, Freeman, S. J., *et al.* 226–227
Dimethylthiourea, Anaesthetic properties of dimethylthiourea, Koblin, D. D., *et al.* 456–458
Dog, A comparison between various hemodynamic parameters reflecting preload during graded hemorrhage in ventilated dogs, Preisman, S., *et al.*, (*ESA*) A.51
——, Acute haemodynamic effect of sodium bicarbonate in canine respiratory or metabolic acidosis, Nishikawa, T. 196–200
——, Does exogenous dopamine reverse cardiovascular depression induced by isoflurane during thoracic epidural blockade? Raner, C., *et al.*, (*ESA*) A.49
——, Endocardial endothelium modulates *in vivo* left ventricular performance, De Hert, S. G., *et al.*, (*ESA*) A.47
——, Lemakalim reverses ventricular conduction impairment induced by a large dose of bupivacaine in anesthetized dogs, de La Coussaye, J. E., *et al.*, (*ESA*) A.121
——, Pharmacokinetics of propofol administered by infusion in dogs undergoing surgery, Nolan, A., *et al.* 546–551
Donors, organ transplantation, Effects of desmopressin (DDAVP) supplementation in brain dead organ donors (BDOD) on early recipient renal function, Guesde, R., *et al.*, (*ESA*) A.79
——, Fiberoptic bronchoscopy in brain dead organ donors, Riou, B., *et al.*, (*ESA*) A.80
Drug delivery, Blended anaesthesia in pediatric major surgery: top-up *vs* epidural continuous infusion, Savoia, G., *et al.*, (*ESA*) A.159
——, Tetanic fade during recovery from vecuronium block: comparison of systemic and isolated forearm administration, Campkin, N. T. A., *et al.* 581–582
——, Treatment of cancer pain with morphine (MO)—A double blind study of extradural (ED) *versus* intramuscular (im) routes of administration, Nath, S., *et al.*, (*ESA*) A.211
Drug delivery, bolus, Influence of cardiac output, injection time and injection volume on the initial mixing of drugs with venous blood after i.v. bolus administration to sheep, Upton, R. N., *et al.* 333–338
——, Prediction of infusion rate of vecuronium to maintain steady state using the bolus test dose technique, Morgan, R. J., *et al.*, (*ARS*) 481P
Drug delivery, computerized, Closed-loop feedback controlled administration of alfentanil during alfentanil–nitrous oxide anaesthesia, Schwilden, H., *et al.* 389–393
——, Comparison of midazolam with propofol for sedation in outpatient bronchoscopy, Crawford, M., *et al.* 419–422
——, Computer-controlled syringe pump improves safety of pharmacokinetic models, Duranteau, R., *et al.*, (*ESA*) A.148
——, Determination of a pharmacokinetic model for propofol induction of anaesthesia, Viviand, X., *et al.*, (*ESA*) A.150
——, Target-controlled intravenous sedation with propofol, Mergaert, C., *et al.*, (*ESA*) A.149
Drug delivery, infusion, Prediction of infusion rate of vecuronium to maintain steady state using the bolus test dose technique, Morgan, R. J., *et al.*, (*ARS*) 481P
Drug delivery, injection speed, Comparison of infusion rates of three i.v. anaesthetic agents for induction in elderly patients, Berthoud, M. C., *et al.* 423–427
——, Different rates of injection of propofol, Goodman, N. W., (*C*) 383
——, Different rates of injection of propofol, Peacock, J. E., *et al.*, (*C*) 383–384
——, Influence of cardiac output, injection time and injection volume on the initial mixing of drugs with venous blood after i.v. bolus administration to sheep, Upton, R. N., *et al.* 333–338
Drug delivery, nasal, Comparison of nasal cannulae with face mask for oxygen administration to postoperative patients, Nolan, K. M., *et al.* 440–442
——, Intranasal fentanyl for breakthrough cancer pain or incident pain, Striebel, W. H., *et al.*, (*ESA*) A.210
——, Intranasal fentanyl for postoperative pain management in an unselected population, Striebel, W. H., *et al.*, (*ESA*) A.209
——, Pharmacokinetics of intranasal fentanyl, Striebel, H. W., *et al.*, (*ESA*) A.208
——, Plasma concentrations of midazolam after i.v., nasal or rectal administration in children, Malinovsky, J.-M., *et al.* 617–620
Drug delivery, oral, Dose dependent effects of oral medication with midazolam, Biro, P., *et al.*, (*ESA*) A.156
——, High dose oral morphine in cancer pain management, Radbruch, L., *et al.*, (*ESA*) A.212
Drug delivery, rectal, Plasma concentrations of midazolam after i.v., nasal or rectal administration in children, Malinovsky, J.-M., *et al.* 617–620
Drug delivery, transdermal, Pharmacokinetic behaviour of transdermal fentanyl, Van Bastelaere, M., *et al.*, (*ESA*) A.146

Education, junior staff, Nine years of clinical experience with 29 gauge spinal needles, Dittmann, M., *et al.*, (*ESA*) A.126
Electrical systems, burns, Electrode burns during local hyperthermia, Stott, D. G., *et al.* 370–371

Neuromuscular block, decamethonium, Comparison of the onset of depolarizing *vs* non-depolarizing block after early tourniquet release in the isolated forearm, Hood, J. R., *et al.*, (*ARS*) 480P
Neuromuscular block, measurement of response, Can repetition of high frequencies stimuli alter the value of 50 and 100 Hz tetanic fade during vecuronium induced neuromuscular blockade? Baurain, M. J., *et al.*, (*ESA*) A.135
——, Comparison between double-burst stimulation and 50, 100 Hz tetanic fade during spontaneous recovery of vecuronium induced neuromuscular blockade, Baurain, M. J., *et al.*, (*ESA*) A.133
——, Monitoring the onset of neuromuscular blockade at the orbicularis oculi can predict good intubating conditions when using 2 × ED$_{95}$ of atracurium, Debaene, B., *et al.*, (*ESA*) A.142
——, Potency estimation of mivacurium: comparison of two different modes of nerve stimulation, Maddineni, V. R., *et al.* 694–695
Neuromuscular block, mivacurium, Neostigmine antagonism of neuromuscular blockade induced by mivacurium, vecuronium and atracurium, Dernovoi, B. S., *et al.*, (*ESA*) A.137
——, Neuromuscular blockade following mivacurium in children during N$_2$O–halothane, Orliaguet, G., *et al.*, (*ESA*) A.163
——, Pharmacokinetics of the isomers of mivacurium chloride in the healthy adult, Head-Rapson, A. G., *et al.*, (*ARS*) 487P
——, Potency estimation of mivacurium: comparison of two different modes of nerve stimulation, Maddineni, V. R., *et al.* 694–695
Neuromuscular block, pancuronium, Cardiovascular effects of a pancuronium–vecuronium mixture, Doyle, M., *et al.*, (*ARS*) 486–487P
——, Lipid solubility of pancuronium and vecuronium determined by n-octanol/water partitioning, Weindlmayr-Goettel, M., *et al.* 579–580
——, Neostigmine and edrophonium antagonism of moderate neuromuscular block induced by pancuronium or tubocurarine, Shorten, G. D., *et al.* 160–162
Neuromuscular block, pipecuronium, Pipecuronium-induced prolongation of vecuronium neuromuscular block, Smith, I., *et al.* 446–448
Neuromuscular block, potentiation, Does nicardipine potentiate the neuromuscular block of atracurium? Bazin, J. E., *et al.*, (*ESA*) A.136
——, Pipecuronium-induced prolongation of vecuronium neuromuscular block, Smith, I., *et al.* 446–448
——, Recoveries of post-tetanic twitch and train-of-four responses after administration of vecuronium with different inhalation anaesthetics and neuroleptanaesthesia, Saitoh, Y., *et al.* 402–404
Neuromuscular block, priming, Onset of action of a small dose of vecuronium, Nathanson, M. H., *et al.*, (*ARS*) 481–482P
——, Priming of atracurium with magnesium, Lampl, E., *et al.*, (*ESA*) A.139
Neuromuscular block, recovery, Can repetition of high frequencies stimuli alter the value of 50 and 100 Hz tetanic fade during vecuronium induced neuromuscular blockade? Baurain, M. J., *et al.*, (*ESA*) A.135
——, Comparison between double-burst stimulation and 50, 100 Hz tetanic fade during spontaneous recovery of vecuronium induced neuromuscular blockade, Baurain, M. J., *et al.*, (*ESA*) A.133
——, Neostigmine antagonism of neuromuscular blockade induced by mivacurium, vecuronium and atracurium, Dernovoi, B. S., *et al.*, (*ESA*) A.137
——, Neuromuscular blockers in day-case surgery: is speed of onset more important than duration of action? Lippmann, M., *et al.*, (*C*) 235
——, Neuromuscular blockers in day-case surgery: is speed of onset more important than duration of action? Mirakhur, R. K., *et al.*, (*C*) 235
——, Recoveries of post-tetanic twitch and train-of-four responses after administration of vecuronium with different inhalation anaesthetics and neuroleptanaesthesia, Saitoh, Y., *et al.* 402–404
——, Recovery of atracurium and vecuronium neuromuscular block in the isolated forearm, Law Min, J.-C., *et al.*, (*ARS*) 480–481P
——, Tetanic fade during recovery from vecuronium block: comparison of systemic and isolated forearm administration, Campkin, N. T. A., *et al.* 581–582
Neuromuscular block, rocuronium, Concentration–effect relationship at the vocal cords and the adductor pollicis following rocuronium administration, Plaud, B., *et al.*, (*ESA*) A.141
——, Neuromuscular blockers in day-case surgery: is speed of onset more important than duration of action? Lippmann, M., *et al.*, (*C*) 235
——, Neuromuscular blockers in day-case surgery: is speed of onset more important than duration of action? Mirakhur, R. K., *et al.*, (*C*) 235
——, Pharmacokinetics of rocuronium (Org 9426) in patients with and without impaired renal function, Cooper, R., *et al.*, (*ARS*) 482P
——, The pharmacokinetics of rocuronium in pediatric patients: a pooled data analysis, Meistelman, C., *et al.*, (*ESA*) A.138
Neuromuscular block, suxamethonium, Comparison of alfentanil with suxamethonium in facilitating nasotracheal intubation in day-case anaesthesia, Alcock, R., *et al.* 34–37
——, Propofol and alfentanil or thiopentone and suxamethonium for tracheal intubation, Beck, G. N., *et al.*, (*ARS*) 483P
Neuromuscular block, tubocurarine, Neostigmine and edrophonium antagonism of moderate neuromuscular

block induced by pancuronium or tubocurarine, Shorten, G. D., *et al.* 160–162
——, Prejunctional action of neostigmine on mouse neuromuscular preparations, Braga, M. F. M., *et al.* 405–410

Neuromuscular block, vecuronium, Can repetition of high frequencies stimuli alter the value of 50 and 100 Hz tetanic fade during vecuronium induced neuromuscular blockade? Baurain, M. J., *et al.*, (*ESA*) A.135
——, Cardiovascular effects of a pancuronium–vecuronium mixture, Doyle, M., *et al.*, (*ARS*) 486–487P
——, Comparison between double-burst stimulation and 50, 100 Hz tetanic fade during spontaneous recovery of vecuronium induced neuromuscular blockade, Baurain, M. J., *et al.*, (*ESA*) A.133
——, Comparison of the onset of depolarizing *vs* non-depolarizing block after early tourniquet release in the isolated forearm, Hood, J. R., *et al.*, (*ARS*) 480P
——, Lipid solubility of pancuronium and vecuronium determined by n-octanol/water partitioning, Weindlmayr-Goettel, M., *et al.* 579–580
——, Lung function after vecuronium pretreatment in elderly patients, Mahajan, R. P., *et al.*, (*ARS*) 482–483P
——, Neostigmine antagonism of neuromuscular blockade induced by mivacurium, vecuronium and atracurium, Dernovoi, B. S., *et al.*, (*ESA*) A.137
——, Neuromuscular blockers in day-case surgery: is speed of onset more important than duration of action? Lippmann, M., *et al.*, (*C*) 235
——, Neuromuscular blockers in day-case surgery: is speed of onset more important than duration of action? Mirakhur, R. K., *et al.*, (*C*) 235
——, Onset of action of a small dose of vecuronium, Nathanson, M. H., *et al.*, (*ARS*) 481–482P
——, Pipecuronium-induced prolongation of vecuronium neuromuscular block, Smith, I., *et al.* 446–448
——, Prediction of infusion rate of vecuronium to maintain steady state using the bolus test dose technique, Morgan, R. J., *et al.*, (*ARS*) 481P
——, Recoveries of post-tetanic twitch and train-of-four responses after administration of vecuronium with different inhalation anaesthetics and neuroleptanaesthesia, Saitoh, Y., *et al.* 402–404
——, Recovery of atracurium and vecuronium neuromuscular block in the isolated forearm, Law Min, J.-C., *et al.*, (*ARS*) 480–481P
——, Reversal of vecuronium induced neuromuscular blockade: no effects of atropine administration timing, Baurain, M. J., *et al.*, (*ESA*) A.134
——, Supra-additivity between atracurium and vecuronium, Meretoja, O. A., *et al.*, (*ESA*) A.140
——, Tetanic fade during recovery from vecuronium block: comparison of systemic and isolated forearm administration, Campkin, N. T. A., *et al.* 581–582

Neuromuscular transmission, Effect of isometric thumb preload on the evoked compound muscle action potential, Kalli, I. 92–93
——, Prejunctional action of neostigmine on mouse neuromuscular preparations, Braga, M. F. M., *et al.* 405–410
——, Tetanic fade during recovery from vecuronium block: comparison of systemic and isolated forearm administration, Campkin, N. T. A., *et al.* 581–582

Non-steroidal anti-inflammatory drugs, Diclofenac and ketoprofen for pain treatment after elective Caesarean section, Rorarius, M. G. F., *et al.* 293–297
——, Ketorolac postoperative analgesia, Al-Hasani, A., (*C*) 112–113
——, Ketorolac postoperative analgesia, Kinsella, J., (*C*) 113
——, Preoperative indomethacin for pain relief after thoracotomy: comparison with postoperative indomethacin, Murphy, D. F., *et al.* 298–300

Oxygen, consumption, Changes in blood lactate, total body oxygen delivery and consumption during liver transplantation, Carrera, J., *et al.*, (*ESA*) A.77
——, Influence of N-acetylcysteine on O_2 consumption and gastric intramucosal pH in septic patients, Spies, C., *et al.*, (*ESA*) A.186
——, Oxygen consumption is dependent upon oxygen delivery in cirrhotics undergoing liver transplantation, Piccinni, P., *et al.*, (*ESA*) A.78
——, The effect of dobutamine and norepinephrine on global and splanchnic O_2 consumption, Meier-Hellmann, A., *et al.*, (*ESA*) A.185

Oxygen, delivery systems, Comparison of nasal cannulae with face mask for oxygen administration to postoperative patients, Nolan, K. M., *et al.* 440–442
——, Extracorporeal membrane oxygenation for postoperative cardiac support in newborn infants: first clinical data, Marcassa, A., *et al.*, (*ESA*) A.168
——, IVOX, Skoyles, J., *et al.*, (*E*) 603–604

Oxygen, inspired concentration, Effect of hyperoxia on the breathing of patients anaesthetized with infusions of propofol, Dow, A. C., *et al.* 532–535
——, Effects of active and passive sighs in normoxia and hyperoxia on the breathing of patients anaesthetized with infusions of propofol, Goodman, N. W., *et al.* 536–541

Oxygen, measurement, Statistical assessment of two methods of clinical measurement, Berridge, J. C., (*C*) 595
——, Statistical assessment of two methods of clinical measurement, Runcie, C. J., (*C*) 595

Oxygen, saturation, Comparison of midazolam with propofol for sedation in outpatient bronchoscopy, Crawford, M., *et al.* 419–422
——, Continuous monitoring of Sp_{O_2} during total intravenous anaesthesia with ketamine and spontaneous ventilation, Joly, L.-M., *et al.*, (*ESA*) A.58
——, Effects of lorazepam on oxygen saturation before cardiac surgery, Pollock, J. S. S., *et al.* 219–220
——, Hypoxic events after general anaesthesia in the recovery room, Degasperi, D., *et al.*, (*ESA*) A.59
——, Influence of anaesthesia on post-operative hypoxaemia, Georgiou, L., *et al.*, (*ESA*) A.60
——, Jugular bulb metabolic monitoring during hyperventilation in severe head trauma patients, De Deyne, C., *et al.*, (*ESA*) A.106
——, Lung function after vecuronium pretreatment in elderly patients, Mahajan, R. P., *et al.*, (*ARS*) 482–483P
——, Preoxygenation and Sp_{O_2} after induction of anaesthesia with propofol and fentanyl, Rittoo, D. B., *et al.*, (*ARS*) 486P
——, Routine preoxygenation: how long before mask anaesthesia? Head-Rapson, A. G., *et al.*, (*ARS*) 488P
——, Sedation with propofol during regional anaesthesia, Arnold, B. D. C., (*C*) 112
——, Statistical assessment of two methods of clinical measurement, Berridge, J. C., (*C*) 595
——, Statistical assessment of two methods of clinical measurement, Runcie, C. J., (*C*) 595

Oxygen, therapy, Comparison of nasal cannulae with face mask for oxygen administration to postoperative patients, Nolan, K. M., *et al.* 440–442

Oxygen, tissue, Influence of norepinephrine therapy on the oxygen supply and lactate extraction rate of the liver in the septic pig, Schäfer, R., *et al.*, (*ESA*) A.184
——, Oxygen consumption is dependent upon oxygen delivery in cirrhotics undergoing liver transplantation, Piccinni, P., *et al.*, (*ESA*) A.78
——, The effect of dobutamine and norepinephrine on global and splanchnic O_2 consumption, Meier-Hellmann, A., *et al.*, (*ESA*) A.185

Oxygen, transport, The effect of dobutamine and norepinephrine on global and splanchnic O_2 consumption, Meier-Hellmann, A., *et al.*, (*ESA*) A.185

Oxygen, uptake, Propofol (2,6 diisopropylphenol) as an antioxidant *in-vitro*: a dose response study, Bennett, S., *et al.*, (*ESA*) A.152
——, Septic shock: effect of a goal-directed therapy on oxygen metabolism and serum cytokine levels, Martin, C., *et al.*, (*ESA*) A.189

Pain, Pre-emptive extradural analgesia, Hardy, P. A. J., (*C*) 493

Pain, acute, Intranasal fentanyl for breakthrough cancer pain or incident pain, Striebel, W. H., *et al.*, (*ESA*) A.210
——, Organization of acute pain services—a low-cost model, Rawal, N., (*ESA*) A.199
——, The value of pre-emptive analgesia in the treatment of postoperative pain, Dahl, J. B., *et al.* 434–439

Pain, chronic, Diaphragmatic function after bupivacaine cervical extradural analgesia for chronic pain therapy, Nyström, E., *et al.*, (*ESA*) A.65
——, High dose oral morphine in cancer pain management, Radbruch, L., *et al.*, (*ESA*) A.212
——, Intranasal fentanyl for breakthrough cancer pain or incident pain, Striebel, W. H., *et al.*, (*ESA*) A.210
——, Intrathecal pain relief in terminally ill cancer patients at home, Wagemans, M. F. M., *et al.*, (*ESA*) A.213
——, Treatment of cancer pain with morphine (MO)—A double blind study of extradural (ED) *versus* intramuscular (im) routes of administration, Nath, S., *et al.*, (*ESA*) A.211

Pain, injection, Alizapride does reduce pain on injection of propofol: comparison with lidocaine, Zaouk, G., *et al.*, (*ESA*) A.11

——, Pain on i.v. injection of metoclopramide, Wilkinson, D. J., *(C)* 239
——, Quality of induction: a clinical comparison of Etomidat-Lipuro® and Hypnomidate®, Wiebalck, A., *et al.*, *(ESA)* A.154
Pain, mechanism, Differential effects of specific delta and kappa opioid antagonists on the bidirectionnal effect of naloxone in arthritic rats, Cattaneo, I., *et al.*, *(ESA)* A.114
——, Pre-emptive analgesia, Dahl, J. B., *et al.*, *(C)* 379
——, Pre-emptive analgesia, Katz, J., *et al.*, *(C)* 378
——, The value of pre-emptive analgesia in the treatment of postoperative pain, Dahl, J. B., *et al.* 434–439
Pain, postoperative, A survey of sleep problems in surgical patients, Beydon, L., *et al.*, *(ESA)* A.4
——, Addition of droperidol to PCA morphine: what is the optimal dose? Lamond, C. T., *et al.*, *(ESA)* A.204
——, Analgesia by wound infiltration before or after surgery in inguinal hernioraphy, Hennart, D., *et al.*, *(ESA)* A.202
——, Diclofenac and ketoprofen for pain treatment after elective Caesarean section, Rorarius, M. G. F., *et al.* 293–297
——, Effect of morphine on a nociceptive flexion reflex in patients with postoperative pain, Chauvin, M., *et al.*, *(ESA)* A.115
——, Efficacy of continuous intercostal bupivacaine for pain relief after thoracotomy, Dryden, C. M., *et al.* 508–510

——, Epidural administration of liposomal bupivacaine for the management of postsurgical pain, Boogaerts, J., *et al.*, *(ESA)* A.200
——, Epidural clonidine analgesia after major gynaecological surgery, Smilov, I., *et al.*, *(ESA)* A.176
——, Evaluation of pain and analgesia in a postanesthesia care unit, Aubrun, F., *et al.*, *(ESA)* A.198
——, Evaluation of the analgesic effect of metoclopramide after opioid-free analgesia, Lisander, B. 631–633
——, Extradural 0.07% bupivacaine for postoperative pain, Slade, J. M., *(ARS)* 478P
——, Intranasal fentanyl for postoperative pain management in an unselected population, Striebel, W. H., *et al.*, *(ESA)* A.209
——, Ketorolac postoperative analgesia, Al-Hasani, A., *(C)* 112–113
——, Ketorolac postoperative analgesia, Kinsella, J., *(C)* 113
——, Organization of acute pain services—a low-cost model, Rawal, N., *(ESA)* A.199
——, Pain relief after anterior cruciate ligament repair, Carroll, P. H., *et al.*, *(C)* 600
——, Pain relief after anterior cruciate ligament repair, Joshi, G. P., *(C)* 600
——, Pain relief for infants undergoing abdominal surgery: comparison of infusions of i.v. morphine and extradural bupivacaine, Wolf, A. R., *et al.* 10–16
——, Partial reversal of the effects of extradural clonidine by oral yohimbine in postoperative patients, Liu, N., *et al.* 515–518
——, Patient-controlled extradural analgesia to compare bupivacaine, fentanyl and bupivacaine with fentanyl in the treatment of postoperative pain, Cooper, D. W., *et al.* 503–507
——, Postoperative analgesia: a two dosage regimens trial for i.m. morphine after early i.v. titration, Butscher, K., *et al.*, *(ESA)* A.201
——, Postoperative analgesia in children, Fell, D., *(E)* 4–5
——, Postoperative pain thresholds, Cook, T. M., *(C)* 110
——, Pre-emptive analgesia, Dahl, J. B., *et al.*, *(C)* 379
——, Pre-emptive analgesia, Katz, J., *et al.*, *(C)* 378
——, Preemptive analgesia with epidural morphine, Nègre, I., *et al.*, *(ESA)* A.203
——, Preoperative indomethacin for pain relief after thoracotomy: comparison with postoperative indomethacin, Murphy, D. F., *et al.* 298–300
——, The value of pre-emptive analgesia in the treatment of postoperative pain, Dahl, J. B., *et al.* 434–439
——, Transthoracic endoscopic sympathectomy, Gilligan, S., *et al.*, *(C)* 491
——, Transthoracic endoscopic sympathectomy, Jedeiken, R., *et al.*, *(C)* 491–492
——, Transthoracic endoscopic sympathectomy, Plastow, S. E., *et al.*, *(C)* 492
——, Ventilatory effects of morphine, pethidine and methadone in children, Hamunen, K. 414–418
Pain, threshold, Alterations in pain threshold and psychomotor response associated with subanaesthetic concentrations of inhalation anaesthetics in humans, Tomi, K., *et al.* 684–686
——, *In vivo* determination of concentration–effect curves of local anaesthetics in man, Wiesemes, R., *et al.* 552–555
——, Postoperative pain thresholds, Cook, T. M., *(C)* 110
Pain, tourniquet, Comparison of the effect of EMLA cream, subcutaneous ring anaesthesia and a double cuff technique in the prevention of tourniquet pain, Tsai, Y.-C., *et al.* 394–396
Pain, visceral, Direct spinal effect of intrathecal and extradural midazolam on visceral noxious stimulation in rabbits, Crawford, M. E., *et al.* 642–646
Parasympathetic nervous system, Effects of surgical stimulation on autonomic reflex function: assessment by changes in heart rate variability, Latson, T. W., *et al.* 301–305
Parasympathetic nervous system, atropine, Reversal of vecuronium induced neuromuscular blockade: no effects of atropine administration timing, Baurain, M. J., *et al.*, *(ESA)* A.134
Parasympathetic nervous system, glycopyrronium, Glycopyrronium prolongs topical anaesthesia of oral mucosa and enhances absorption of lignocaine, Watanabe, H., *et al.* 94–95
Partial pressure, arterial–end-tidal, Components of the inspiratory–arterial isoflurane partial pressure difference, Landon, A. J., *et al.* 605–611
——, Relationship between arterial $P\text{co}_2$ (Pa_{CO_2}) and end tidal CO_2 (ETco_2) recorded through a laryngeal mask (LMA) in children breathing spontaneously, Van Obbergh, L. J., *et al.*, *(ESA)* A.164
Partial pressure, carbon dioxide, Is correlation of arterial and end-tidal carbon dioxide pressure during inhalation anaesthesia better with laryngeal mask as compared to face mask? Ivens, D., *et al.*, *(ESA)* A.17
Partial pressure, inert gases, Asymmetry of uptake and washout of inert gases—lessons learnt in an anaesthetic department, Flook, V., *(ARS)* 487–488P
——, Hyperbaric decompression bubble formation—building on the Mapleson model of gas dynamics, Flook, V., *et al.*, *(ARS)* 474–475P
Partial pressure, isoflurane, Brain partial pressures of isoflurane and nitrous oxide, Petersen-Felix, S., *et al.*, *(C)* 704–705
——, Brain partial pressures of isoflurane and nitrous oxide, Thornton, C., *et al.*, *(C)* 705
——, Components of the inspiratory–arterial isoflurane partial pressure difference, Landon, A. J., *et al.* 605–611
Partial pressure, nitrous oxide, Brain partial pressures of isoflurane and nitrous oxide, Petersen-Felix, S., *et al.*, *(C)* 704–705
——, Brain partial pressures of isoflurane and nitrous oxide, Thornton, C., *et al.*, *(C)* 705
Partial pressure, oxygen, Early postperfusion assessment of gas exchange and postoperative extubation outcome following coronary artery surgery, Knapik, P., *et al.*, *(ESA)* A.61
Phaeochromocytoma, Use of transoesophageal echocardiography to manage beta-adrenoceptor block and assess left ventricular function in a patient with phaeochromocytoma, Ryan, T., *et al.* 101–103
Pharmacodynamics, Comparison of the onset of depolarizing *vs* non-depolarizing block after early tourniquet release in the isolated forearm, Hood, J. R., *et al.*, *(ARS)* 480P
——, Concentration–effect relationship at the vocal cords and the adductor pollicis following rocuronium administration, Plaud, B., *et al.*, *(ESA)* A.141
——, Effect of age, gender and anaesthetic technique on the pharmacodynamics of atracurium, Parker, C. J. R., *et al.* 38–41
——, I.v. bolus administration of subconvulsive doses of lignocaine to conscious sheep: relationships between myocardial pharmacokinetics and pharmacodynamics, Huang, Y. F., *et al.* 556–561
——, Monitoring the onset of neuromuscular blockade at the orbicularis oculi can predict good intubating conditions when using $2 \times \text{ED}_{95}$ of atracurium, Debaene, B., *et al.*, *(ESA)* A.142
——, Neuromuscular blockade following mivacurium in children during N_2O–halothane, Orliaguet, G., *et al.*, *(ESA)* A.163
——, Neuromuscular blockers in day-case surgery: is speed of onset more important than duration of action? Lippmann, M., *et al.*, *(C)* 235
——, Neuromuscular blockers in day-case surgery: is speed of onset more important than duration of action? Mirakhur, R. K., *et al.*, *(C)* 235
——, Onset of action of a small dose of vecuronium, Nathanson, M. H., *et al.*, *(ARS)* 481–482P

——, Pharmacokinetic/pharmacodynamic modelling of atracurium, Beemer, G. H., *et al.*, (*C*) 111
——, Pharmacokinetic/pharmacodynamic modelling of atracurium, Fisher, D. M., (*C*) 110–111
——, Pharmacokinetic/pharmacodynamic modelling of atracurium, Parker, C. J. R., *et al.*, (*C*) 111–112
——, Pharmacokinetics and pharmacodynamics of ketamine enantiomers in surgical patients using a stereoselective analytical method, Geisslinger, G., *et al.* 666–671
——, Propofol and alfentanil mixture, Sandin, R., (*C*) 382–383
——, Propofol and alfentanil mixture, Taylor, I. N., *et al.*, (*C*) 383
——, Relationship between volume of distribution of atracurium and body weight, Parker, C. J. R., *et al.* 443–445
Pharmacokinetics, alfentanil, Pharmacokinetic behaviour of transdermal fentanyl, Van Bastelaere, M., *et al.*, (*ESA*) A.146
——, Pharmacokinetics and effects of i.m. alfentanil as premedication for outpatient cataract surgery, Ali-Melkkilä, T., *et al.*, (*ESA*) A.145
Pharmacokinetics, atracurium, Mortality in ITU patients receiving neuromuscular blocking drugs, Hunter, J. M., *et al.*, (*C*) 238–239
——, Pharmacokinetic/pharmacodynamic modelling of atracurium, Beemer, G. H., *et al.*, (*C*) 111
——, Pharmacokinetic/pharmacodynamic modelling of atracurium, Fisher, D. M., (*C*) 110–111
——, Pharmacokinetic/pharmacodynamic modelling of atracurium, Parker, C. J. R., *et al.*, (*C*) 111–112
——, Relationship between volume of distribution of atracurium and body weight, Parker, C. J. R., *et al.* 443–445
Pharmacokinetics, bupivacaine, Plasma concentrations of bupivacaine and its enantiomers during continuous extrapleural intercostal nerve block, Berrisford, R. G., *et al.* 201–204
——, Slow-release effect of pH-adjusted bupivacaine: pharmacokinetic demonstration, Benhamou, D., *et al.*, (*ESA*) A.120
Pharmacokinetics, fentanyl, Pharmacokinetics of intranasal fentanyl, Striebel, H. W., *et al.*, (*ESA*) A.208
Pharmacokinetics, flumazenil, Pharmacokinetics of flumazenil and midazolam, Jones, R. D. M., *et al.* 286–292
Pharmacokinetics, glycine, Glycine and its metabolites during and after intrauterine YAG laser surgery, Van Boven, M. J., *et al.*, (*ESA*) A.87
Pharmacokinetics, heart, I.v. bolus administration of subconvulsive doses of lignocaine to conscious sheep: myocardial pharmacokinetics, Huang, Y. F., *et al.* 326–332
——, I.v. bolus administration of subconvulsive doses of lignocaine to conscious sheep: relationships between myocardial pharmacokinetics and pharmacodynamics, Huang, Y. F., *et al.* 556–561
Pharmacokinetics, ketamine, Pharmacokinetics and pharmacodynamics of ketamine enantiomers in surgical patients using a stereoselective analytical method, Geisslinger, G., *et al.* 666–671
Pharmacokinetics, lignocaine, I.v. bolus administration of subconvulsive doses of lignocaine to conscious sheep: myocardial pharmacokinetics, Huang, Y. F., *et al.* 326–332
——, I.v. bolus administration of subconvulsive doses of lignocaine to conscious sheep: relationships between myocardial pharmacokinetics and pharmacodynamics, Huang, Y. F., *et al.* 556–561
Pharmacokinetics, liver, Pharmacokinetics of rocuronium (Org 9426) in patients with and without impaired renal function, Cooper, R., *et al.*, (*ARS*) 482P
Pharmacokinetics, lung, Sufentanil first-pass pulmonary uptake at three different steady state concentrations of the drug, Boer, F., *et al.*, (*ESA*) A.147
Pharmacokinetics, midazolam, Midazolam premedication: a forensic approach to pharmacokinetics and amnesia, Motsch, J., *et al.*, (*ESA*) A.155
——, Pharmacokinetics of flumazenil and midazolam, Jones, R. D. M., *et al.* 286–292
——, Prolonged (> 1 week) sedation with midazolam in ICU patients: efficacy, safety and pharmacokinetics, Heytens, L., *et al.*, (*ESA*) A.178
Pharmacokinetics, mivacurium, Pharmacokinetics of the isomers of mivacurium chloride in the healthy adult, Head-Rapson, A. G., *et al.*, (*ARS*) 487P
Pharmacokinetics, models, A physiological model for the distribution of injected agents, with special reference to pethidine, Davis, N. R., *et al.* 248–258
——, Effect of age, gender and anaesthetic technique on the pharmacodynamics of atracurium, Parker, C. J. R., *et al.* 38–41
——, Why not model physiologically? Sear, J. W., (*E*) 243–245
Pharmacokinetics, morphine-6-glucuronide, Morphine-6-glucuronide disposition in renal impairment, Hanna, M. H., *et al.* 511–514
Pharmacokinetics, obesity, Perioperative management of the obese patient, Shenkman, Z., *et al.* 349–359
Pharmacokinetics, propofol, Pharmacokinetics of propofol administered by infusion in dogs undergoing surgery, Nolan, A., *et al.* 546–551
——, Pharmacokinetics of propofol and its conjugates after continuous infusion in normal and renal failure patients, Nathan, N., *et al.*, (*ESA*) A.151
Pharmacokinetics, rocuronium, Concentration–effect relationship at the vocal cords and the adductor pollicis following rocuronium administration, Plaud, B., *et al.*, (*ESA*) A.141
——, Pharmacokinetics of rocuronium (Org 9426) in patients with and without impaired renal function, Cooper, R., *et al.*, (*ARS*) 482P
——, The pharmacokinetics of rocuronium in pediatric patients: a pooled data analysis, Meistelman, C., *et al.*, (*ESA*) A.138
Pharmacokinetics, solubility, Lipid solubility of pancuronium and vecuronium determined by n-octanol/water partitioning, Weindlmayr-Goettel, M., *et al.* 579–580
Pharmacokinetics, stereoisomers, Pharmacokinetics and pharmacodynamics of ketamine enantiomers in surgical patients using a stereoselective analytical method, Geisslinger, G., *et al.* 666–671
——, Pharmacokinetics of the isomers of mivacurium chloride in the healthy adult, Head-Rapson, A. G., *et al.*, (*ARS*) 487P
——, Plasma concentrations of bupivacaine and its enantiomers during continuous extrapleural intercostal nerve block, Berrisford, R. G., *et al.* 201–204
Pharmacokinetics, uptake, Components of the inspiratory–arterial isoflurane partial pressure difference, Landon, A. J., *et al.* 605–611
——, Influence of cardiac output, injection time and injection volume on the initial mixing of drugs with venous blood after i.v. bolus administration to sheep, Upton, R. N., *et al.* 333–338
——, Onset of action of a small dose of vecuronium, Nathanson, M. H., *et al.*, (*ARS*) 481–482P
——, Plasma concentrations of midazolam after i.v., nasal or rectal administration in children, Malinovsky, J.-M., *et al.* 617–620
——, Relationship between volume of distribution of atracurium and body weight, Parker, C. J. R., *et al.* 443–445
——, Sufentanil first-pass pulmonary uptake at three different steady state concentrations of the drug, Boer, F., *et al.*, (*ESA*) A.147
——, The pharmacokinetics of rocuronium in pediatric patients: a pooled data analysis, Meistelman, C., *et al.*, (*ESA*) A.138
——, Ultrasound measurement of muscle thickness in the estimation of fat free mass, Watt, T., *et al.*, (*ARS*) 477P
Pharmacology, 5-HT antagonists, Comparison of ondansetron, metoclopramide and droperidol for the prophylaxis of emetic symptoms after gynecological laparoscopic procedures, Geiger, C., *et al.*, (*ESA*) A.14
——, Double-blind comparison of ondansetron, droperidol and saline for prevention of nausea & vomiting after orthopaedic surgery, Gan, T. J., *et al.*, (*ESA*) A.13
——, Ondansetron 4 mg *vs* droperidol 1.25 mg in the prophylaxis of postoperative nausea and vomiting after alfentanil-supplemented inhalation anaesthesia, Alon, E., *et al.*, (*ESA*) A.12
Pharmacology, alizapride, Alizapride does reduce pain on injection of propofol: comparison with lidocaine, Zaouk, G., *et al.*, (*ESA*) A.11
Pharmacology, blood loss, Perioperative blood loss, Appadu, B., (*C*) 492–493
Pharmacology, bupivacaine, Motor blockade and absence of local nerve toxicity induced by liposomal bupivacaine injected into the axillary brachial plexus of rabbits, Legros, F. J., *et al.*, (*ESA*) A.122
Pharmacology, captopril, Does captopril modify the arterial response to vasopressor substances? Le Pelley, E., *et al.*, (*ESA*) A.48
Pharmacology, clonidine, Clonidine in paediatric caudal anaesthesia, Jamali, S., *et al.*, (*ESA*) A.160
——, Effects of epidural clonidine on anaesthetic requirements and postoperative analgesia, Samsó, E., *et al.*, (*ESA*) A.205
——, Epidural clonidine and myocardial ischaemia after

abdominal aortic surgery, Fulgencio, J. P., *et al.*, (*ESA*) A.42
——, Partial reversal of the effects of extradural clonidine by oral yohimbine in postoperative patients, Liu, N., *et al.* 515–518
——, Preoperative clonidine improves postoperative renal function in CABG patients, Kulka, P. J., *et al.*, (*ESA*) A.143
Pharmacology, dexmedetomidine, Dexmedetomidine does not exercise its anesthetic action through GABA, Salonen, M., *et al.*, (*ESA*) A.113
Pharmacology, dimethylthiourea, Anaesthetic properties of dimethylthiourea, Koblin, D. D., *et al.* 456–458
Pharmacology, dobutamine, Metabolic effects of dobutamine, Campbell, I. T., *et al.*, (*C*) 236
——, Metabolic effects of dobutamine, Oh, T. E., *et al.*, (*C*) 237–238
——, Metabolic effects of dobutamine, Smith, D. C., *et al.*, (*C*) 236–237
Pharmacology, dose-response, *In vivo* determination of concentration–effect curves of local anaesthetics in man, Wiesemes, R., *et al.* 552–555
——, Potency estimation of mivacurium: comparison of two different modes of nerve stimulation, Maddineni, V. R., *et al.* 694–695
——, Propofol (2,6 diisopropylphenol) as an antioxidant *in-vitro*: a dose response study, Bennett, S., *et al.*, (*ESA*) A.152
Pharmacology, enoximone, Haemodynamic changes produced by inhalation anaesthetics in the presence of phosphodiesterase inhibition, Molter, G., *et al.* 428–433
Pharmacology, guanfacine, Effects of oral preoperative guanfacine on anesthetics requirements, Engelman, E., *et al.*, (*ESA*) A.144
Pharmacology, isoboles, Synergy and isoboles, Calvey, T. N., (*E*) 246–247
Pharmacology, lemakalim, Lemakalim reverses ventricular conduction impairment induced by a large dose of bupivacaine in anesthetized dogs, de La Coussaye, J. E., *et al.*, (*ESA*) A.121
Pharmacology, metoclopramide, Evaluation of the analgesic effect of metoclopramide after opioid-free analgesia, Lisander, B. 631–633
——, Pain on i.v. injection of metoclopramide, Wilkinson, D. J., (*C*) 239
Pharmacology, midazolam, Direct spinal effect of intrathecal and extradural midazolam on visceral noxious stimulation in rabbits, Crawford, M. E., *et al.* 642–646
Pharmacology, morphine, Treatment of cancer pain with morphine (MO)—A double blind study of extradural (ED) *versus* intramuscular (im) routes of administration, Nath, S., *et al.*, (*ESA*) A.211
Pharmacology, N-acetylcysteine, Influence of N-acetylcysteine on O_2 consumption and gastric intramucosal pH in septic patients, Spies, C., *et al.*, (*ESA*) A.186
Pharmacology, phosphodiesterase inhibitors, Haemodynamic changes produced by inhalation anaesthetics in the presence of phosphodiesterase inhibition, Molter, G., *et al.* 428–433
Pharmacology, preservatives, Functional recovery after 24 h preservation of rabbit hearts in University Wisconsin solution, Fellahi, J. L., *et al.*, (*ESA*) A.44
Pharmacology, propofol, Propofol (2,6 diisopropylphenol) as an antioxidant *in-vitro*: a dose response study, Bennett, S., *et al.*, (*ESA*) A.152
Pharmacology, ryanodine, Comparison of *in vitro* contracture testing with ryanodine, halothane and caffeine in malignant hyperthermia and other neuromuscular disorders, Hopkins, P. M., *et al.* 397–401
Pharmacology, sodium bicarbonate, Acute haemodynamic effect of sodium bicarbonate in canine respiratory or metabolic acidosis, Nishikawa, T. 196–200
Pharmacology, synergism, Dexmedetomidine does not exercise its anesthetic action through GABA, Salonen, M., *et al.*, (*ESA*) A.113
——, Does exogenous dopamine reverse cardiovascular depression induced by isoflurane during thoracic epidural blockade? Raner, C., *et al.*, (*ESA*) A.49
——, Effect of age, gender and anaesthetic technique on the pharmacodynamics of atracurium, Parker, C. J. R., *et al.* 38–41
——, Supra-additivity between atracurium and vecuronium, Meretoja, O. A., *et al.*, (*ESA*) A.140
——, Synergy and isoboles, Calvey, T. N., (*E*) 246–247
Pharmacology, vecuronium, Tetanic fade during recovery from vecuronium block: comparison of systemic and isolated forearm administration, Campkin, N. T. A., *et al.* 581–582
Pharmacology, yohimbine, Partial reversal of the effects of extradural clonidine by oral yohimbine in postoperative patients, Liu, N., *et al.* 515–518
Physics, baricity, Hypertonic solutions in acute massive haemorrhage, Brimacombe, J., *et al.*, (*C*) 705
——, Hypertonic solutions in acute massive haemorrhage, Park, G. R., (*C*) 706
Physics, fluid dynamics, Evidence for dynamic phenomena in residual tracheal tube biofilm, Inglis, T. J. J. 22–24
Pig, Aprotinin does not decrease surgical bleeding and could promote arterial thrombosis in the pig: a prospective randomized, blind, study, Samama, C. M., *et al.*, (*ESA*) A.100
——, Does captopril modify the arterial response to vasopressor substances? Le Pelley, E., *et al.*, (*ESA*) A.48
——, Influence of cervicothoracic epidural anaesthesia (C-TEA) on left ventricular (LV) contractility—an experimental study in pigs with autonomous blockade, Reiz, S., *et al.*, (*ESA*) A.52
——, Influence of norepinephrine therapy on the oxygen supply and lactate extraction rate of the liver in the septic pig, Schäfer, R., *et al.*, (*ESA*) A.184
——, Midazolam prevents ketamine-induced stimulation of cerebral metabolism, Åkeson, J., *et al.*, (*ESA*) A.111
——, Pre- and intraoperative prevention by β-blockers, propranolol and esmolol, of ischaemia-induced ventricular fibrillation, Freysz, M., *et al.*, (*ESA*) A.46
Placenta, drug distribution, Intermittent *vs* continuous extradural infusion of bupivacaine during labour, Laishley, R. S., (*C*) 490
Polypeptides, aprotinin, Aprotinin does not decrease surgical bleeding and could promote arterial thrombosis in the pig: a prospective randomized, blind, study, Samama, C. M., *et al.*, (*ESA*) A.100
——, Blood requirements reduction in orthotopic liver transplantation with aprotinin, Monedero, P., *et al.*, (*ESA*) A.98
——, High dose aprotinin *versus* desmo-pressin acetate treatment in cardiac surgery, Hidalgo, F., *et al.*, (*ESA*) A.99
——, Use of aprotinine during cytoreductive surgery of ovarian cancer, Lequeau, F., *et al.*, (*ESA*) A.97
Polypeptides, cytokines, Laparoscopic *vs* open cholecystectomy, Jakeways, M. S. R., *et al.*, (*C*) 597
——, Metabolic effects of cholecystectomy, Joris, J., (*C*) 494
——, Metabolic effects of cholecystectomy, McMahon, A. J., *et al.*, (*C*) 493–494

——, Septic shock: effect of a goal-directed therapy on oxygen metabolism and serum cytokine levels, Martin, C., *et al.*, (*ESA*) A.189
Polypeptides, endothelin, Is the vasoconstrictive effect of cyclosporine mediated by endothelin in kidney transplantation? Mouquet, C., *et al.*, (*ESA*) A.84
Porphyria, Xylometazoline and porphyria, Platt, N. D., (*C*) 491
Position, effects, Influence of pneumoperitoneum and posture on hemodynamic and stress responses during anaesthesia for laparoscopic surgery, Odeberg, S., *et al.*, (*ESA*) A.34
——, Influence of posture on the respiratory mechanics during anesthesia, Engelman, E., *et al.*, (*ESA*) A.56
Position, head, Influence of posture on the respiratory mechanics during anesthesia, Engelman, E., *et al.*, (*ESA*) A.56
Position, lithotomy, Fresh gas requirements of an enclosed afferent reservoir breathing system in anaesthetized, spontaneously breathing adults, Barrie, J. R., *et al.* 468–470
Position, prone, Effect of three different surgical prone positions on lung volumes in healthy, awake volunteers, Hennessy, N., *et al.*, (*ARS*) 475P
——, The respiratory compliance in normal and obese subjects during anaesthesia, Mulazzi, D., *et al.*, (*ESA*) A.54
Position, supine, The respiratory compliance in normal and obese subjects during anaesthesia, Mulazzi, D., *et al.*, (*ESA*) A.54
Potency, anaesthetic, Addition of droperidol to PCA morphine: what is the optimal dose? Lamond, C. T., *et al.*, (*ESA*) A.204
——, Clonal variation in response to enflurane anaesthesia with *Daphnia magna*, Myles, A. P., *et al.*, (*ARS*) 476–477P
——, Comparison of infusion rates of three i.v. anaesthetic agents for induction in elderly patients, Berthoud, M. C., *et al.* 423–427
——, Pharmacokinetics of propofol administered by infusion in dogs undergoing surgery, Nolan, A., *et al.* 546–551
——, Propofol (2,6 diisopropylphenol) as an antioxidant *in-*

vitro: a dose response study, Bennett, S., *et al.*, (*ESA*) A.152
Potency, anaesthetic, age factors, Different rates of injection of propofol, Goodman, N. W., (*C*) 383
——, Different rates of injection of propofol, Peacock, J. E., *et al.*, (*C*) 383–384
Potency, anaesthetic, ED$_{50}$, Anaesthetic properties of dimethylthiourea, Koblin, D. D., *et al.* 456–458
Potency, anaesthetic, MAC, Isoproterenol reverses the MAC decreasing effect of esmolol in rats, Perel, A., *et al.*, (*ESA*) A.117
——, Minimum alveolar concentration of sevoflurane in elderly patients, Nakajima, R., *et al.* 273–275
Potency, analgesic, Closed-loop feedback controlled administration of alfentanil during alfentanil–nitrous oxide anaesthesia, Schwilden, H., *et al.* 389–393
——, Extradural 0.07% bupivacaine for postoperative pain, Slade, J. M., (*ARS*) 478P
——, Relative efficacy and potency of nalmefene, a long-acting opioid antagonist, Watson, N. A., *et al.*, (*ARS*) 479P
Potency, drug, Anq 9040: effect of twice the ED$_{95}$ dose, Munday, I. T., *et al.*, (*ARS*) 480P
——, Onset of action of a small dose of vecuronium, Nathanson, M. H., *et al.*, (*ARS*) 481–482P
——, Potency estimation of mivacurium: comparison of two different modes of nerve stimulation, Maddineni, V. R., *et al.* 694–695
Potency, drug, age factors, Onset of action of a small dose of vecuronium, Nathanson, M. H., *et al.*, (*ARS*) 481–482P
Potency, drug, tolerance, Prolonged (> 1 week) sedation with midazolam in ICU patients: efficacy, safety and pharmacokinetics, Heytens, L., *et al.*, (*ESA*) A.178
Pregnancy, Antepartum assessment for anaesthesia, Cody, M., *et al.*, (*C*) 116
——, Antepartum assessment for anaesthesia, Reynolds, F., (*C*) 116
——, Antepartum assessment for anaesthesia, Uncles, D. R., *et al.*, (*C*) 116
——, Comparison of automatic oscillometric arterial pressure measurement with conventional auscultatory measurement in the labour ward, Hasan, M. A., *et al.* 141–144
——, Neonatal glycemia: does the maternal i.v. fluid regimen during labor make a difference? Menigaux, C., *et al.*, (*ESA*) A.175
——, Spread of spinal anaesthesia for Caesarean section in singleton and twin pregnancies, Jawan, B., *et al.* 639–641
Pregnancy, abortion, Anaesthetic implications of the anti-cardiolipin antibody syndrome, Menon, G., *et al.* 587–590
Premedication, Pharmacokinetics and effects of i.m. alfentanil as premedication for outpatient cataract surgery, Ali-Melkkilä, T., *et al.*, (*ESA*) A.145
Premedication, clonidine, Preoperative clonidine improves postoperative renal function in CABG patients, Kulka, P. J., *et al.*, (*ESA*) A.143
Premedication, glycopyrronium, Glycopyrronium prolongs topical anaesthesia of oral mucosa and enhances absorption of lignocaine, Watanabe, H., *et al.* 94–95
Premedication, guanfacine, Effects of oral preoperative guanfacine on anesthetics requirements, Engelman, E., *et al.*, (*ESA*) A.144
Premedication, lorazepam, Effects of lorazepam on oxygen saturation before cardiac surgery, Pollock, J. S. S., *et al.* 219–220
Premedication, midazolam, Dose dependent effects of oral medication with midazolam, Biro, P., *et al.*, (*ESA*) A.156
——, Midazolam premedication: a forensic approach to pharmacokinetics and amnesia, Motsch, J., *et al.*, (*ESA*) A.155
——, Plasma concentrations of midazolam after i.v., nasal or rectal administration in children, Malinovsky, J.-M., *et al.* 617–620
Premedication, nifedipine, Effect of premedication with nifedipine on intraoperative hypothermia, Vassilieff, N., *et al.*, (*ESA*) A.71
Principles and Protocols in Intensive Care, Willatts, S. M., *et al.*, (editors), (*R*) 239
Protein, albumin, Hepatic elimination of diazepam: interactions with albumin, desflurane and sevoflurane, Dale, O., *et al.* 454–455
Protein, amino acids, Glycine and its metabolites during and after intrauterine YAG laser surgery, Van Boven, M. J., *et al.*, (*ESA*) A.87
Protein, binding, Hepatic elimination of diazepam: interactions with albumin, desflurane and sevoflurane, Dale, O., *et al.* 454–455
Protein, globulin, Carbohydrate deficient transferrin: a new copredictor of alcoholism related postoperative complications? Heil, T., *et al.*, (*ESA*) A.88
Protein, metabolism, Effect of recombinant human growth hormone (HGH) on protein metabolism in surgical patients, Carli, F., *et al.*, (*ESA*) A.86
Protein, plasma, Surfactant and adult respiratory distress syndrome, Jacobson, W., *et al.* 522–526
Psychological responses, Alterations in pain threshold and psychomotor response associated with subanaesthetic concentrations of inhalation anaesthetics in humans, Tomi, K., *et al.* 684–686
——, Comparison of the sedative and amnesic effects of midazolam and propofol, Polster, M. R., *et al.* 612–616
——, Dose dependent effects of oral medication with midazolam, Biro, P., *et al.*, (*ESA*) A.156
——, Plasma catecholamines and neonatal condition after induction of anaesthesia with propofol or thiopentone at Caesarean section, Gin, T., *et al.* 311–316
——, Validation of coherent frequency of the EEG as a measure of consciousness during anaesthesia, Munglani, R., *et al.*, (*ARS*) 483–484P
Psychological responses, unconscious perception, Comparison of the sedative and amnesic effects of midazolam and propofol, Polster, M. R., *et al.* 612–616

Rabbit, Direct spinal effect of intrathecal and extradural midazolam on visceral noxious stimulation in rabbits, Crawford, M. E., *et al.* 642–646
——, Effects of hypertonic saline on coronary blood flow and myocardial performance of a blood-perfused, isolated rabbit heart, Delayance, S., *et al.*, (*ESA*) A.45

——, Partial reversal of the effects of extradural clonidine by oral yohimbine in postoperative patients, Liu, N., *et al.* 515–518

Sympathetic nervous system, dexmedetomidine, Dexmedetomidine does not exercise its anesthetic action through GABA, Salonen, M., *et al.*, (*ESA*) A.113

Sympathetic nervous system, dobutamine, Metabolic effects of dobutamine, Campbell, I. T., *et al.*, (*C*) 236

——, Metabolic effects of dobutamine, Oh, T. E., *et al.*, (*C*) 237–238

——, Metabolic effects of dobutamine, Smith, D. C., *et al.*, (*C*) 236–237

——, The effect of dobutamine and norepinephrine on global and splanchnic O_2 consumption, Meier-Hellmann, A., *et al.*, (*ESA*) A.185

Sympathetic nervous system, dopamine, Does exogenous dopamine reverse cardiovascular depression induced by isoflurane during thoracic epidural blockade? Raner, C., *et al.*, (*ESA*) A.49

Sympathetic nervous system, ephedrine, *In vitro* effect of ephedrine, adrenaline, noradrenaline and isoprenaline on halothane-induced contractures in skeletal muscle from patients potentially susceptible to malignant hyperthermia, Urwyler, A., *et al.* 76–79

——, Spinal anesthesia for C section: addition of phenylephrine to ephedrine for prevention of maternal hypotension, Thirion, A.-V., *et al.*, (*ESA*) A.172

Sympathetic nervous system, esmolol, Effect of esmolol *versus* lidocaine on intracranial pressure and haemodynamic responses to laryngoscopy and intubation, Samaha, T., *et al.*, (*ESA*) A.118
——, Isoproterenol reverses the MAC decreasing effect of esmolol in rats, Perel, A., *et al.*, (*ESA*) A.117
——, Use of esmolol in the postbypass management of hypertrophic obstructive cardiomyopathy, Ooi, L. G., *et al.* 104–106
——, Use of transoesophageal echocardiography to manage beta-adrenoceptor block and assess left ventricular function in a patient with phaeochromocytoma, Ryan, T., *et al.* 101–103
Sympathetic nervous system, isoprenaline, *In vitro* effect of ephedrine, adrenaline, noradrenaline and isoprenaline on halothane-induced contractures in skeletal muscle from patients potentially susceptible to malignant hyperthermia, Urwyler, A., *et al.* 76–79
——, Isoproterenol reverses the MAC decreasing effect of esmolol in rats, Perel, A., *et al.*, (*ESA*) A.117
Sympathetic nervous system, noradrenaline, Effect of fentanyl on $[^3H]$noradrenaline uptake in isolated neuronal cell preparations, Atcheson, R., *et al.*, (*ARS*) 485P
——, *In vitro* effect of ephedrine, adrenaline, noradrenaline and isoprenaline on halothane-induced contractures in skeletal muscle from patients potentially susceptible to malignant hyperthermia, Urwyler, A., *et al.* 76–79
——, Influence of norepinephrine therapy on the oxygen supply and lactate extraction rate of the liver in the septic pig, Schäfer, R., *et al.*, (*ESA*) A.184
——, The effect of dobutamine and norepinephrine on global and splanchnic O_2 consumption, Meier-Hellmann, A., *et al.*, (*ESA*) A.185
Sympathetic nervous system, pharmacology, Does captopril modify the arterial response to vasopressor substances? Le Pelley, E., *et al.*, (*ESA*) A.48
Sympathetic nervous system, phenylephrine, Spinal anesthesia for C section: addition of phenylephrine to ephedrine for prevention of maternal hypotension, Thirion, A.-V., *et al.*, (*ESA*) A.172
Sympathetic nervous system, sympathoadrenal responses, Haemodynamic and catecholamine responses to induction of anaesthesia and tracheal intubation: comparison between propofol and thiopentone, Lindgren, L., *et al.* 306–310
——, Plasma catecholamines and neonatal condition after induction of anaesthesia with propofol or thiopentone at Caesarean section, Gin, T., *et al.* 311–316
Sympathetic nervous system, xylometazoline, Xylometazoline and porphyria, Platt, N. D., (*C*) 491
Sympathetic nervous system, yohimbine, Partial reversal of the effects of extradural clonidine by oral yohimbine in postoperative patients, Liu, N., *et al.* 515–518
Systemic lupus erythematosus, Anaesthetic implications of the anti-cardiolipin antibody syndrome, Menon, G., *et al.* 587–590

Techniques in Extracorporeal Circulation, 3rd Edn, Kay, P. H., (editor), (*R*) 239–240
Temperature, body, An investigation into the effect of passive and active cutaneous warming devices on intraoperative body temperature in elderly patients, Bennet, J., *et al.*, (*ESA*) A.73
——, Core-peripheral temperature difference in early *vs* later extubation after coronary artery surgery, Knapik, P., *et al.*, (*ESA*) A.69
——, Effect of premedication with nifedipine on intraoperative hypothermia, Vassilieff, N., *et al.*, (*ESA*) A.71
——, Effect of radiant heat on the metabolic cost of postoperative shivering, Sharkey, A., *et al.* 449–450
——, Effectiveness of core warming on net transfer of body heat across the skin, Kulkarni, P., *et al.*, (*ESA*) A.70
——, Evaluation of a forced-air warmer (Bair-Hugger) in maintaining body temperature in infants during cleft palate surgery, Murat, I., *et al.*, (*ESA*) A.166
——, Evaluation of the efficacy of forced-air warmer (Bair Hugger) during spinal surgery in children, Murat, I., *et al.*, (*ESA*) A.165
——, Preoperative skin-surface warming reduces intraoperative hypothermia, Camus, Y., *et al.*, (*ESA*) A.72
Temperature, metabolism, Effect of radiant heat on the metabolic cost of postoperative shivering, Sharkey, A., *et al.* 449–450
Temperature, regulation, Clinical evaluation of the oesophageal heat exchanger in the prevention of perioperative hypothermia, Kulkarni, P., *et al.* 216–218
——, Fentanyl, as pethidine, inhibits post anaesthesia shivering, Alfonsi, P., *et al.*, (*ESA*) A.74
Temperature, skin, An investigation into the effect of passive and active cutaneous warming devices on intraoperative body temperature in elderly patients, Bennet, J., *et al.*, (*ESA*) A.73
——, Preoperative skin-surface warming reduces intraoperative hypothermia, Camus, Y., *et al.*, (*ESA*) A.72
The Complete Recovery Room Book, Hatfield, A., *et al.*, (*R*) 709
The Oxford Textbook of Clinical Pharmacology and Drug Therapy, 2nd Edn, Graham-Smith, D. G., *et al.*, (*R*) 601
Theories of anaesthetic action, cellular mechanisms, Halothane enhances forskolin stimulated cyclic adenosine-3′,5′-monophosphate formation in human neuroblastoma cells, Hirst, R. A., *et al.*, (*ARS*) 486P
——, Membrane action of volatile anaesthetics: effect of halothane on microviscosity, Appadu, B., *et al.*, (*ARS*) 477P
——, Nitrous oxide induced neuronal depression: modification through benzodiazepine receptors, Dzoljic, M., *et al.*, (*ESA*) A.112
Theories of anaesthetic action, molecular, Effects of midazolam and flunitrazepam on the release of dopamine from rat striatum measured by *in vivo* microdialysis, Takada, K., *et al.* 181–185
Theories of analgesic action, Differential effects of alfentanil, fentanyl, pethidine and lignocaine administered intrathecally on nociceptive responses evoked by low and high frequency stimulation of somatic nerves, Wang, C., *et al.* 63–69
——, Effect of fentanyl on $[^3H]$noradrenaline uptake in isolated neuronal cell preparations, Atcheson, R., *et al.*, (*ARS*) 485P
——, Effects of morphine and its metabolites on opiate receptor binding and cyclic adenosine-3′,5′-monophosphate (cAMP) formation in human neuroblastoma cells, Lambert, D. G., *et al.*, (*ARS*) 475–476P
Thromboxane, Inhibition of increase of blood thromboxane concentration by acetylsalicylic acid after release of tourniquet in lower extremity operations, Ojanen, R., *et al.*, (*ESA*) A.94
——, The relationship between cardiopulmonary bypass related immunologic effects and complement, thromboxane and leucocyte parameters, Durak, P., *et al.*, (*ESA*) A.96
Toxicity, The management of acute poisoning, Collee, G. G., *et al.* 562–573
Toxicity, hepatic, Halothane, metabolite-induced antibodies and hepatotoxicity, Kenna, J. G., *et al.*, (*ARS*) 484–485P
——, Hepatotoxicity of volatile anaesthetics, Elliott, R. H., *et al.* 339–348
Toxicity, local anaesthetics, Motor blockade and absence of local nerve toxicity induced by liposomal bupivacaine injected into the axillary brachial plexus of rabbits, Legros, F. J., *et al.*, (*ESA*) A.122
——, Plasma concentrations of bupivacaine and its enantiomers during continuous extrapleural intercostal nerve block, Berrisford, R. G., *et al.* 201–204
Toxicity, metabolites, Halothane, metabolite-induced antibodies and hepatotoxicity, Kenna, J. G., *et al.*, (*ARS*) 484–485P
Transesophageal Echocardiography, Clements, F. M., *et al.*, (editors), (*R*) 708
Transfusion, Blood loss during total hip replacement, Jones, N. O., *et al.*, (*C*) 235–236
——, Blood loss during total hip replacement, McSwiney, M., (*C*) 236
——, Effects of recombinant-human erythropoietin on postoperative transfusion requirements in subjects undergoing major orthopaedic surgery, Faris, P. P., *et al.*, (*ESA*) A.101
——, Hypertonic solutions in acute massive haemorrhage, Brimacombe, J., *et al.*, (*C*) 705
——, Hypertonic solutions in acute massive haemorrhage, Park, G. R., (*C*) 706
——, The role of recombinant growth factors in transfusion medicine, Goodnough, L. T. 80–86
Transfusion, autotransfusion, Acute preoperative plasmapheresis during cardiac surgery, Armellin, G., *et al.*, (*ESA*) A.104
——, Effects of postoperative auto-transfusion in spine surgery, Riou, B., *et al.*, (*ESA*) A.103
——, Preoperative autotransfusion in emergency surgery for spine trauma, Riou, B., *et al.*, (*ESA*) A.102

Uterus, oxytocin, Intermittent *vs* continuous extradural infusion of bupivacaine during labour, Eddleston, J. M., (*C*) 490
——, Intermittent *vs* continuous extradural infusion of bupivacaine during labour, Laishley, R. S., (*C*) 490

——, Mechanisms of ECG changes during Caesarean section (CS)—a hypothesis, Svanström, M., *et al.*, (*ESA*) A.177

Veins, cannulation, The pressor response to venous cannulation: attenuation by prior infiltration with local anaesthetic, Langham, B. T., *et al.* 519–521
Veins, complications, Possible venous air embolism with a new water jet dissector, Smith, J. A. S. 466–467
——, Quality of induction: a clinical comparison of Etomidat-Lipuro® and Hypnomidate®, Wiebalck, A., *et al.*, (*ESA*) A.154
Veins, jugular, cannulation, Use of ultrasound to evaluate internal jugular vein anatomy and to facilitate central venous cannulation in paediatric patients, Alderson, P. J., *et al.* 145–148
Veins, veno-venous bypass, Shunt flow and caval pressure gradient during veno-venous bypass in human orthotopic liver transplantation, Scherer, R. U., *et al.* 689–690
Ventilation, airway pressure, Extra inspiratory work of breathing imposed by cricothyrotomy devices, Ooi, R., *et al.* 17–21
Ventilation, analgesics, effects of, Ventilatory effects of morphine, pethidine and methadone in children, Hamunen, K. 414–418
Ventilation, apnoea, An alternative method of increasing $P\text{co}_2$ using apnoea and continuous positive airway pressure, Karlsten, R., *et al.* 411–413
Ventilation, carbon dioxide response, An alternative method of increasing $P\text{co}_2$ using apnoea and continuous positive airway pressure, Karlsten, R., *et al.* 411–413
Ventilation, continuous positive pressure, An alternative method of increasing $P\text{co}_2$ using apnoea and continuous positive airway pressure, Karlsten, R., *et al.* 411–413
Ventilation, failure, Muscular paralysis and ventilatory failure caused by hyperkalaemia, Freeman, S. J., *et al.* 226–227
Ventilation, fresh gas flow, Fresh gas requirements of an enclosed afferent reservoir breathing system in anaesthetized, spontaneously breathing adults, Barrie, J. R., *et al.* 468–470
Ventilation, hyperventilation, Jugular bulb metabolic monitoring during hyperventilation in severe head trauma patients, De Deyne, C., *et al.*, (*ESA*) A.106
Ventilation, mechanical, An alternative method of increasing $P\text{co}_2$ using apnoea and continuous positive airway pressure, Karlsten, R., *et al.* 411–413
——, Comparison of pressure support ventilation provided by two ICU ventilators, Kalfon, P., *et al.*, (*ESA*) A.182
——, Comparison of spontaneous sighs and manual inflations in anaesthetized patients breathing air and oxygen, Dow, A. C., *et al.*, (*ARS*) 474P
——, Continuous monitoring of the ventilatory mechanics during anaesthesia & intensive care, Py, C., *et al.*, (*ESA*) A.57
——, Determinants of systolic pressure variation in patients ventilated after vascular surgery, Beaussier, M., *et al.*, (*ESA*) A.37
